- Ten complexes of snRNPs and protein splicing factors have been distinguished during a splicing cycle (Figure 9-13).
- Several RNA helicases are required in the splicing process. They utilize energy from ATP hydrolysis to drive the transesterification reactions in the direction of exon ligation.
- Since the basic catalytic mechanism of the spliceosome is performed by two Mg^{2+} ions bound by U6 (Figure 9-14c), and the substrate splice sites are delivered to the RNA-based active site by interactions with both snRNAs and proteins, the spliceosome is considered to be a *protein-directed metalloribozyme.*
- Following RNA splicing in vertebrates, a specific set of hnRNP proteins remain bound to the spliced RNA approximately 20 nucleotides $5'$ to each exon-exon junction forming an *exon-junction complex (EJC)*. As discussed in later sections, EJCs participate in mRNA export to the cytoplasm and in quality-control surveillance mechanisms that eliminate improperly processed mRNAs.
- The $3'$ end of an mRNA is generated by cleavage of the pre-mRNA at a poly(A) site, an AAUAAA 10-35 bases upstream of the cleavage site and a GU- or U-rich sequence ~ 20

nucleotides downstream from the cleavage site. A poly(A) polymerase in a multisubunit cleavage-polyadenylation complex that performs the cleavage reactions adds a poly(A) tail of ~ 250 nucleotides in vertebrates, ~ 100 nucleotides in yeast, to the $3'$ end. The poly(A) tail is then immediately bound by nuclear poly(A) binding protein (PABPN1), protecting the $3'$ end from digestion by an exosome.

9.2 Regulation of Pre-mRNA Processing

Now that we've seen how pre-mRNAs are processed into mature, functional mRNAs, we consider how regulation of this process can contribute to control of gene expression. Recall from Figure 7-3 that multicellular eukaryotes contain both simple and complex transcription units encoded in their DNA. The primary transcripts produced from the former contain one poly(A) site and exhibit only one pattern of RNA splicing, even if multiple introns are present; thus simple transcription units encode a single mRNA. In contrast, the primary transcripts produced from complex transcription units (~95 percent of all human transcription units) can be processed in alternative ways to yield different mRNAs that encode distinct proteins (see Figure 7-3). This process of **alternative RNA splicing** greatly expands the number of functionally distinct proteins encoded by the ~19,000 human genes (where one gene equals one transcription unit for a primary transcript). The increase in complexity of mRNAs resulting from alternative splicing in metazoans reaches its zenith in the central nervous system, where regulation of complex patterns of alternative RNA splicing is required for generating synaptic connections between neurons, and consequently, appropriate behavior (see Chapter 23).

Additional Nuclear Proteins Contribute to Splice-Site Selection in the Long Pre-mRNAs of Humans and Other Vertebrates

How are splice sites recognized during processing of eukaryotic pre-mRNAs so that exons can be joined precisely to generate long open reading frames? As mentioned above, almost all 5′ splice sites in yeast conform to the sequence/GUAUGU, which is perfectly complementary to the sequence at the 5′ end of U1 snRNA (Figure 9-9). As first shown in the compensatory base pairing experiment described in Figure 9-9b, Watson-Crick base pairing between U1 snRNA and the first six bases of the intron are required for pre-mRNA splicing. In yeast, perfect complementarity between a six-base sequence near the middle of U2 snRNA and the branch-point A sequence near the 3′ end of the intron (Figures 9-9a and 9-12) is also essential for splicing. Only ∼5 percent of *S. cerevisiae* genes contain an intron, and most of these contain a single intron. In this organism, pre-mRNA splice sites are selected primarily by base-pairing to U1 snRNA for the 5′ splice site at the beginning of an intron, and to U2 snRNA at the branch-point sequence just upstream of the 3′ splice site (Figure 9-9a). However, in humans, RNA sequences at 5′ and 3′ splice sites and the branch site are far more degenerate (Figure 9-12). Most introns begin with 5′ GU and end with 3′ AG preceded by a polypyrimidine tract of 10–12 bases, and a

very short, degenerate six-base sequence encompassing the branch-point A. These consensus splice-site sequences are so degenerate that they cannot be used to predict splice sites in the human genome sequence; the vast majority of sequences that match these degenerate sequences are *not* used as splice sites. Consequently, other aspects of human pre-mRNA sequences must contribute to splice site selection.

Extensive mutational analysis of sequences within ~200 bp of splice sites of a number of specific mammalian genes identified sequences in some pre-mRNAs required for splicing in addition to the short, degenerate 5′ splice sites, branch point, and 3′ splice sites (Figure 9-12, *bottom*). These were different specific sequences in different genes within ~200 bases of the 5′ and 3′ splice sites. Characterization of nuclear RNA-binding proteins that bind to these regulatory sequences in RNA, and cDNA cloning and sequencing of related genes, have led to the discovery of at least 1500 human RNA-binding proteins that bind to short 3–4 base RNA sequences. These are hnRNP proteins discussed earlier, and, consequently, consist of one or more RNA-binding domains (RRMs, Figure 9-6) fused to other functional domains. These additional functional domains often either stimulate or inhibit splicing at a splice site within ~200 bases of the binding site for the regulatory hnRNP. This allows relatively short exons (average length ~150 bases in humans) to be recognized in long primary transcripts that can have introns of tens of kb. This is because the splice sites are determined by the interactions of

these RNA-binding proteins with specific sequences in the pre-mRNA in addition to the interactions of the snRNAs with 5′ splice sites and branch points, and of the U2AF protein splicing factor with 3′ splice sites. The RNA-sequences bound by RNA-binding proteins that stimulate RNA splicing are referred to as **splicing enhancers**, and the RNA-sequences bound by RNA-binding proteins that inhibit RNA splicing are referred to as **splicing silencers**.

In humans and other metazoans, the information for defining some splice sites is encoded by splicing enhancers within the sequence of an exon, consequently called *exonic splicing enhancers*. A subset of hnRNP proteins called **SR proteins**, bind exonic splicing enhancers. SR proteins contain one or more RRM RNA-binding domain. They also contain intrinsically disordered regions of polypeptide rich in arginine (R) and serine (S) residues, called *RS domains*, which can interact with RS domains in other RNA-binding proteins. When bound to exonic splicing enhancers, SR proteins mediate the cooperative binding of U1 snRNP to a 5′ splice site and U2 snRNP to a branch point, through a network of protein-protein interactions that span the exon (Figure 9-16). The complex of SR proteins, snRNPs, and other splicing factors (e.g., U2AF) that assemble across an exon, called a **cross-exon recognition complex**, permits precise specification of some exons in long pre-mRNAs. Many other exons are properly spliced without the assistance of SR proteins because they are demarcated by *constitutive splice sites* with good

complementarity to U1 and U2 snRNAs and polypyrimidine tracts and 3′ splice site RNA sequences with high affinity for U2AF.

FIGURE 9-16 Exon recognition through cooperative binding of SR proteins and splicing factors to pre-mRNA. The correct 5′-GU and 3′-AG splice sites are recognized by splicing factors on the basis of their proximity to exons. The exons contain exonic splicing enhancers (ESEs) that are binding sites for SR proteins. When bound to ESEs, the SR proteins interact with one another and promote the cooperative binding of the U1 snRNP to the 5′ splice site of the downstream intron, SF1 and then the U2 snRNP to the branch point of the upstream intron, the 65- and 35-kD subunits of U2AF to the pyrimidine-rich region and AG 3′ splice site, respectively, of the upstream intron, and other splicing factors (not shown). The resulting RNA-protein cross-exon recognition complex spans an exon and activates the correct splice sites for RNA splicing. Note that the U1 and U2 snRNPs in this unit do not become part of the same spliceosome. The U2 snRNP on the right forms a spliceosome with the U1 snRNP bound to the 5′ end of the same intron. The U1 snRNP shown on the right forms a spliceosome with the U2 snRNP bound to the branch point of the downstream intron (not shown), and the U2 snRNP on the left forms a spliceosome with a U1 snRNP bound to the 5′ splice site of the upstream intron (not shown). Double-headed arrows indicate protein-protein interactions. See T. Maniatis, 2002, *Nature* **418**:236; see also S. M. Berget, 1995, *J. Biol. Chem.* **270**:2411.

This participation of regulatory proteins in the selection of 5′ and 3′ splice sites allows metazoans to regulate the use of [alternative splice sites]. The sequences of the first cDNAs cloned, including mRNAs for alpha and beta globins, antibody light chains, and

chicken ovalbumin, revealed only a single type of spliced mRNA expressed from the genes encoding them. However, this is a very unusual situation in vertebrates that applies to these unusually abundant mRNAs expressed in highly specialized cell types. Extensive cDNA cloning and sequencing and comparison to genomic DNA sequence has revealed that ~95 percent of mammalian mRNAs are processed from primary transcripts that are alternatively spliced into more than one type of mRNA, often in a cell-type-specific manner, as for fibronectin (Figure 5-28). This greatly increases the total number of distinct proteins encoded in metazoans. Furthermore, by regulating the expression and activities of these RNA-binding proteins that regulate RNA splicing, different mammalian cell types can express different mRNA isoforms from the same transcription unit, and hence different protein isoforms, contributing to the distinct functions of different cell types.

Expression and Function of Related K^+-Channel Protein Isoforms in Vertebrate Inner Ear Hair Cells

As mentioned earlier, alternative RNA splicing is most extensive in the vertebrate nervous system. A good example of how alternative RNA splicing regulates the function of a protein central to neuron function is found in the inner ear of vertebrates. Individual ciliated neurons called *hair cells* respond most strongly to a specific

frequency of sound. Cells tuned to low frequency ($\sim 50\,\mathrm{Hz}$) are found at one end of the tubular cochlea that makes up the inner ear; cells responding to high frequency ($\sim 5000\,\mathrm{Hz}$) are found at the other end (Figure 9-17a). Cells in between the ends respond to a gradient of frequencies between these extremes. One component in the tuning of hair cells in reptiles and birds is the opening of K^+ ion channels in response to increased intracellular Ca^{2+} concentrations. The Ca^{2+} concentration at which the channel opens determines the frequency with which the membrane potential oscillates and hence the frequency to which the cell is tuned.

FIGURE 9-17 Function of alternative splicing in the perception of sounds of different frequency. (a) The chicken cochlea, a 5-mm-long tube, contains an epithelium of auditory hair cells that are tuned to a gradient of vibrational frequencies from 50 Hz at the apical end (*left*) to 5000 Hz at the basal end (*right*). (b) The Ca^{2+}-activated K1 channel contains seven transmembrane a helices (S0–S6), which associate to form the channel. The cytosolic domain, which includes four hydrophobic regions (S7–S10), regulates opening of the channel in response to Ca^{2+}. Isoforms of the channel, encoded by alternatively spliced mRNAs produced

from the same primary transcript, open at different Ca^{2+} concentrations and thus respond to different frequencies. Red numbers refer to regions where alternative splicing produces different amino acid sequences in the various isoforms. See K. P. Rosenblatt et al., 1997, *Neuron* **19**:1061.

The gene encoding this Ca^{2+}-activated K^+ channel is expressed as multiple, alternatively spliced mRNAs. The various proteins encoded by these alternative mRNAs open at different Ca^+ concentrations. Hair cells with different response frequencies express different isoforms of the channel protein depending on their position along the length of the cochlea. The sequence variation in the protein is very complex: there are at least eight regions in the mRNA where alternative exons are utilized, permitting the expression of 576 possible isoforms (Figure 9-17b). PCR analysis of mRNAs from individual hair cells has shown that each hair cell expresses a mixture of different alternative Ca^{2+}-activated K^+-channel mRNAs, with different forms predominating in different cells according to their position along the cochlea. This remarkable arrangement suggests that splicing of the Ca^{2+}-activated K^+-channel pre-mRNA is regulated in response to extracellular signals that inform the cell of its position along the cochlea.

Other studies demonstrated that splicing at one of the alternative splice sites in the Ca^{2+}-activated K^+-channel pre-mRNA in the rat is suppressed when a specific protein kinase is activated by neuron depolarization in response to synaptic activity from interacting neurons. This observation raises the possibility that a splicing

repressor specific for this site may be activated when it is phosphorylated by this protein kinase, whose activity in turn is regulated by synaptic activity. Since hnRNP and SR proteins are extensively modified by phosphorylation and other post-translational modifications, it seems likely that complex regulation of alternative RNA splicing through post-translational modifications of splicing factors has a significant function in modulating neuron function.

Regulation of RNA Splicing Through Splicing Enhancers and Silencers Controls *Drosophila* Sexual Differentiation

One of the earliest and best understood examples of regulated alternative splicing of pre-mRNA came from studies of sexual differentiation in *Drosophila*. Genes required for normal *Drosophila* sexual differentiation were first characterized by isolating *Drosophila* mutants defective in the process. When the proteins encoded by the wild-type genes were characterized biochemically, two of them were found to regulate a cascade of alternative RNA splicing in *Drosophila* embryos. Subsequent research provided insight into how these proteins regulate RNA processing and ultimately lead to the expression of one or the other of the two sex-specific transcriptional

repressors that suppress the development of characteristics of the opposite sex.

The Sxl protein, encoded by the *sex-lethal* gene, is the first protein to act in the cascade (Figure 9-18). The Sxl protein is present only in female embryos. Early in development, the *Sxl* gene is transcribed from a promoter that functions only in early female embryos. Later in development, this female-specific promoter is shut off and another promoter for *sex-lethal* becomes active in both male and female embryos. However, in the absence of early Sxl protein, the *sex-lethal* pre-mRNA in male embryos is spliced to produce an mRNA that contains a stop codon early in the sequence (Figure 9-18a, blue shading). The net result is that male embryos produce no functional Sxl protein either early or later in development.

FIGURE 9-18 Cascade of regulated splicing that controls sex determination in *Drosophila* embryos. For clarity, only the exons (boxes) and introns (black lines) where regulated splicing occurs are shown. Splicing is indicated by red dashed lines above (female) and blue dashed lines below (male) the pre-mRNAs. Vertical red lines in exons indicate in-frame stop codons, which prevent synthesis of functional protein. Only female embryos produce functional Sxl protein, which represses splicing between exons 2 and 3 in sxl pre-mRNA (a) and between exons 1 and 2 in tra pre-mRNA (b). (c) In contrast, the cooperative binding of Tra protein and two SR proteins, Rbp1 and Tra2, activates splicing between exons 3 and 4 and cleavage/polyadenylation (A_n) at the 3′ end of exon 4 in dsx pre-mRNA in female embryos. In male embryos, which lack functional Tra, the SR proteins do not bind to exon 4, and consequently exon 3 is spliced to exon 5. The distinct Dsx proteins produced in female and male embryos as the result of this cascade of regulated splicing repress transcription of genes required for sexual differentiation of the opposite sex. See M. J. Moore et al., 1993, in R. Gesteland and J. Atkins, eds., *The RNA World*, Cold Spring Harbor Press, pp. 303–357.

In contrast, the Sxl protein expressed in early female embryos directs splicing of the *sex-lethal* pre-mRNA so that a functional *sex-lethal* mRNA is produced (Figure 9-18a). Sxl accomplishes this by binding to a sequence in the pre-mRNA near the 3′ end of the intron between exon 2 and exon 3, thereby blocking the proper association of U2AF and U2 snRNP with the branch-point A and the 3′ AG (Figure 9-16). As a consequence, the U1 snRNP bound to the 3′ end of exon 2 assembles into a spliceosome with U2 snRNP bound to the branch point at the 3′ end of the intron between exons 3 and 4, leading to splicing of exon 2 to exon 4 and skipping of exon 3 (Figure 9-18a). The binding site for Sxl in the Sxl pre-mRNA is called an

intronic splicing silencer because of its location in an intron and its function in blocking, or "silencing," use of a splice site. The resulting female-specific *sex-lethal* mRNA is translated into functional Sxl protein, which reinforces its own expression in female embryos by continuing to cause skipping of exon 3. The absence of Sxl protein in male embryos allows the inclusion of exon 3 and, consequently, of the stop codon that prevents translation of functional Sxl protein.

Sxl protein also regulates alternative RNA splicing of the *transformer* gene pre-mRNA, the second gene in the regulatory cascade (Figure 9-18b). In male embryos, where no Sxl is expressed, *tra* exon 1 is spliced to *tra* exon 2, which contains a stop codon that prevents synthesis of a functional *transformer* protein, very similar to the inhibition of Sxl protein in male cells (Figure 9-18a). In female embryos, however, binding of Sxl protein to an intronic splicing silencer at the 3′ end of the intron between exons 1 and 2 blocks binding of U2AF at this site. The interaction of Sxl with *transformer* pre-mRNA is mediated by two RRM domains in the Sxl protein (see Figure 9-6b). When Sxl is bound, U2AF binds to a lower affinity site farther 3′ in the pre-mRNA. As a result, exon 1 is spliced to this alternative 3′ splice site, eliminating exon 2 with its stop codon. The resulting female-specific *transformer* mRNA, which contains additional constitutively spliced exons, is translated into functional Transformer (Tra) protein.

In the last step in the regulatory cascade, Tra protein regulates the alternative processing of pre-mRNA transcribed from the *double-sex* gene (Figure 9-18c). In female embryos, a complex of Tra and two constitutively expressed proteins, Rbp1 and Tra2, directs splicing of exon 3 to exon 4 and also promotes cleavage/polyadenylation at the alternative poly(A) site at the 3′ end of exon 4 — leading to a short, female-specific version of the Dsx protein. In male embryos, which produce no Tra protein, exon 4 is skipped, so that exon 3 is spliced to exon 5. Exon 5 is constitutively spliced to exon 6, which is polyadenylated at its 3′ end — leading to a longer, male-specific version of the Dsx protein. The RNA sequence to which Tra binds in exon 4 is called an *exonic splicing enhancer* since it enhances splicing at a nearby splice site.

As a result of this cascade of regulated RNA processing depicted in Figure 9-18, different Dsx proteins are expressed in male and female embryos. The male Dsx protein is a transcriptional repressor that inhibits the expression of genes required for female development. Conversely, the female Dsx protein represses transcription of genes required for male development. In wild-type *Drosophila*, no Sxl protein is expressed in cells of male embryos, whereas it is expressed in female embryos. This is an example of "on-off switch" regulation. The initial expression of Sxl in early female embryos positively regulates its own expression. Other examples of nuclear RNA-binding proteins that generate switch-like control of alternative

RNA splicing in neurons have been identified and termed *master splicing factors.*

Figure 9-19 illustrates how the Tra/Tra2/Rbp1 complex is thought to interact with *double-sex (dsx)* pre-mRNA. Rbp1 and Tra2 are SR proteins, but they do not interact with exon 4 in the absence of the Tra protein. Tra protein interacts with Rbp1 and Tra2, resulting in the cooperative binding of all three proteins to six exonic splicing enhancers in exon 4. The bound Tra2 and Rbp1 proteins then promote the binding of U2AF and U2 snRNP to the 3′ end of the intron between exons 3 and 4 (see Figure 9-17). The Tra/Tra2/Rbp1 complexes may also enhance binding of the cleavage/polyadenylation complex (Figure 9-15) to the 3′ end of exon 4.

FIGURE 9-19 Model of splicing activation by Tra protein and the SR proteins Rbp1 and Tra2. In female *Drosophila* embryos, splicing of exons 3 and 4 in dsx pre-mRNA is activated by binding of Tra/Tra2/Rbp1 complexes to six sites in exon 4. Because Rbp1

and Tra2 cannot bind to the pre-mRNA in the absence of Tra, exon 4 is skipped in male embryos. See the text for discussion. A_n represents $3'$ polyadenylation. See T. Maniatis and B. Tasic, 2002, *Nature* **418**:236.

Splicing Repressors and Activators Control Splicing at Alternative Sites

As is evident from Figure 9-18, the *Drosophila* Sxl protein and Tra protein have opposite effects: Sxl prevents splicing, causing exons to be skipped, whereas Tra promotes splicing. The action of similar proteins may explain the cell-type-specific expression of fibronectin isoforms in humans. For instance, an Sxl-like splicing repressor expressed in hepatocytes might bind to splice sites for the EIIIA and EIIIB exons in the fibronectin pre-mRNA, causing them to be skipped during RNA splicing (Figure 5-28). Alternatively, a Tra-like splicing activator expressed in fibroblasts might activate the splice sites associated with the fibronectin EIIIA and EIIIB exons, leading to inclusion of these exons in the mature mRNA. Experimental examination in some systems has revealed that inclusion of an exon in some cell types versus skipping of the same exon in other cell types results from the combined influence of several splicing repressors and enhancers. RNA binding sites for repressors can also occur in exons, where they are called *exonic splicing silencers.* And binding sites for splicing activators, usually SR proteins, can also occur in introns, where they are called *intronic splicing enhancers.*

Expression of *Dscam* Isoforms in *Drosophila* Retinal Neurons

The most extreme example of regulated alternative RNA processing yet uncovered occurs in expression of the *Dscam* gene in *Drosophila*. Mutations in this gene interfere with the normal synaptic connections made between axons and dendrites during fly development. Analysis of the *Dscam* gene showed that it contains 95 alternatively spliced exons that could be spliced to generate 38,016 possible isoforms (Figure 9-20)! One of 12 possible exons encoding domain Ig2 of the protein is included in each Dscam mRNA. One of 48 possible exons encoding domain Ig3 is included in each Dscam mRNA, and one of 33 possible exons encoding domain Ig7 and one of 2 possible exons encoding the Dscam transmembrane domain are included in each Dscam RNA. Exons diagrammed at the top as vertical black lines are constitutively spliced into all Dscam mRNAs. As a result, the Dscam pre-mRNA is processed into one of $12 \times 48 \times 33 \times 2 = 38{,}016$ possible isoforms. *Drosophila* mutants with a version of the gene that can be spliced in only about 22,000 different ways have specific defects in connectivity between neurons. These results indicate that expression of most of the possible *Dscam* isoforms through regulated RNA splicing helps to specify the tens of millions of different specific synaptic connections between neurons in the *Drosophila* brain. In other words, the correct wiring of neurons in the brain requires regulated RNA splicing.

FIGURE 9-20 The *Drosophila Dscam* gene is processed into a vast number of alternative isoforms. *Dscam* encodes a cell surface protein on neurons. The protein (*bottom*) is composed of 10 different immunoglobulin domains (ovals), six different fibronectin type III domains (rectangles), one transmembrane domain (yellow), and a C-terminal cytoplasmic domain. One of 12 possible Ig2 domains, one of 48 possible Ig3 domains, one of 33 possible Ig7 domains, and one of two possible transmembrane domains, each encoded by one exon, are included in the protein because of the alternative RNA splicing diagrammed at the top. The fully processed mRNA contains one of the alternative exons encoding an Ig2 domain diagrammed in light blue in genomic DNA, one of the alternative exons encoding Ig3 shown in green in genomic DNA, and one of the exons shown in yellow. The exons shown in black are constitutively spliced into each of the messages, generating $12 \times 48 \times 33 \times 2 = 38{,}016$ possible isoforms. See M. R. Sawaya et al., 2008, *Cell* **134**:1007.

Abnormal RNA Splicing and Disease

Multiple examples of human diseases result from abnormalities in RNA splicing. Here we look at examples of mutations that affect exon definition and defects in microexon splicing.

Mutations Affecting Exon Definition Cause Disease

Mutations that affect exon definition are responsible for approximately 15 percent of the single-base-pair mutations that cause human genetic diseases. Some single-base-pair mutations occur in 5′ or 3′ splice sites, often resulting in the use of nearby alternative *cryptic* splice sites present in the normal gene sequence. In the absence of the normal splice site, the cross-exon recognition complex (Figure 9-16) recognizes these alternative sites, which generally are a poorer match to consensus splice-site sequences than the splice site in the wild-type gene that was mutated. Other mutations that cause abnormal splicing result in a new 5′- or 3′-consensus sequence in a pre-mRNA that becomes recognized in place of the normal splice site. This generally results in processing of an abnormal mRNA that does not encode a functional protein. Finally, some mutations can interfere with binding of a pre-mRNA to a specific SR protein. These mutations interfere with the assembly of a cross-exon recognition complex on the mutated exon, and thus lead to exon skipping.

Understanding the mechanisms of exon definition has led to strategies to treat Duschenne Muscular Dystrophy (DMD). Mutations in the sex-linked DMD gene encoded on the X-chromosome are responsible for muscular dystrophy in approximately one in 5000 males, making it one of the most common human genetic diseases. The gene encodes dystrophin, a protein that participates in linking the actin-cytoskeleton to the muscle cell plasma membrane (see

Figure 20-39). When dystrophin is defective, the connection is weakened and muscle cell contraction by movement of actin fibers damages the plasma membrane leading to apoptosis in the mutant muscle cells. DMD mutations in many patients result from a frame shift or stop codon in a DMD exon that evolved from exon duplication (e.g., the tan-colored exons in the fibronectin gene in Figure 5-28). Synthetic oligonucleotides that hybridize to the 5′ splice site of the exon with the mutation prevent U1 snRNP from binding to the 5′ splice site and cause skipping of the mutant exon and in-frame splicing of the preceding exon to the exon following the mutant exon. The resulting mRNA lacks any chain terminating mutations. It encodes a protein lacking one copy of the repeated protein domain, but that protein functions almost as well as the wild-type protein. Current work to develop more efficient membrane-permeant synthetic oligonucleotide derivatives and delivery methods are an active area of research for treatment of DMD due to mutations in repeated exons arising from exon duplication. ■

Spinal Muscular Atrophy is one of the most common genetic causes of childhood mortality. This disease results from mutations in a region of the genome containing two closely related genes, *SMN1* and *SMN2*, that arose by gene duplication during human evolution. *SMN2* encodes a protein identical with *SMN1*; however, correctly spliced *SMN2* mRNA is expressed at a much lower level than *SMN1* mRNA because of a mutation in an exonic splicing

enhancer in the duplicated *SMN2* gene. This mutation resulted in a synonymous codon that does not change the encoded amino acid sequence but does inhibit binding of an SR protein to this region of the *SMN2* pre-mRNA. This leads to skipping of the exon during processing of most *SMN2* primary transcripts because a cross-exon-recognition complex (Figure 9-16) cannot assemble across the affected exon, and consequently cannot stimulate association of U1 snRNP and U2 snRNP with 5′ and 3′ splice sites for this exon in the *SMN2* pre-mRNA. This has little consequence in unaffected individuals because most Smn protein is expressed from the *SMN1* gene.

Genetic studies in the mouse indicate that expression of some Smn protein is required for normal mammalian embryonic development. In the mouse, there is only one *Smn* gene. Mouse embryos with inactivating mutations in both the maternal and paternal copies of the *Smn* gene die early during embryogenesis. However, heterozygous mutants that retain one functional copy of the *Smn* gene develop normally because the lower level of Smn protein expressed from the single copy of the functional gene is sufficient for viability. In other words, inactivating mutations in the mouse *Smn* gene are recessive, as is the case for the majority of protein-coding genes.

The human disease spinal muscular atrophy results when a patient inherits inactivating mutations in both the maternal and paternal

alleles of *SMN1,* the gene that expresses most Smn protein. In these patients, the low level of Smn protein translated from the small fraction of *SMN2* mRNA that is correctly spliced is sufficient to maintain cell viability during embryogenesis and fetal development. However, it is not sufficient to maintain viability of spinal cord motor neurons in childhood, resulting in their death and the associated disease. ■

Microexons and Their Association with Autism Spectrum Disorder

Several types of alternative pre-mRNA splicing have been observed in vertebrate cells (Figure 9-21a). The most common and extensively conserved type of alternatively spliced exons in the central nervous system (CNS) are called **microexons** because they are unusually short: 3 to 27 bases long in multiples of three so that they maintain the reading frames of up- and downstream exons of more typical longer lengths (average ∼150 bases in humans). The discovery of these microexons was surprising because their very short length was expected to prevent the previously understood standard cross-exon recognition complex interactions needed for exon definition (Figure 9-16). The short stretches of amino acids encoded by microexons (1–9 amino acids) generally reside on protein surfaces that participate in protein-protein interactions, and are significantly enriched in genes with critical functions in synaptic biology (Figure 9-21b). Of critical importance here, ∼1/3 of patients with autism

spectrum disorder (ASD) exhibit abnormally low levels of microexon splicing in the CNS.

FIGURE 9-21 Splicing changes in autism spectrum disorder (ASD). (a) Types of alternative splicing. Thin black lines indicate splicing between the indicated splice sites. RNA sequencing analyses (RNA-seq) revealed that cassette exons and microexons (3–27 nucleotides) are much more common forms of alternative RNA splicing in the normal human central nervous system than alternative $5'$ and $3'$ splice sites, retained introns, or complex events. In one-third of patients with autism spectrum disorder (ASD), more skipping of cassette exons and microexons are observed than in normals. Abnormalities in the frequency of splicing of alternative $5'$ and $3'$ splice sites are observed only rarely in ASD. Complex splicing events, while present, occur at too low an incidence to determine if their incidence is altered significantly in ASD patients. (b) Genes containing microexons with abnormal inclusion in ASD patients are listed in the context of molecular hubs of ASD pathogenesis (colored boxes) or their functions in neuronal biology (grey box).

[Data from M. Quesnel-Vallières et al., 2019, *Nat. Rev. Genet.* **20**:51.]

Further research on the mechanism underlying this defect in microexon splicing focused on a particular, neuron-specific SR-protein, SRRM4. Human SRRM4 mRNA was expressed at low level compared to normal in the same $\sim 1/3$ of ASD patients with abnormally low levels of included microexons. Further, the number of microexons that were skipped in these patients correlated with the severity of the decrease in SRRM4 expression. The importance of SRRM4 in some forms of ASD was further supported by genetic experiments in mice. Homozygous knock-out of the *Srrm4* gene in mice is lethal in most pups due to postnatal defects in respiration linked to abnormal innervation of the diaphragm and other neurological defects. Heterozygous *Srrm4* +/- mice are viable, but they express approximately one-half the level of Srrm4 mRNA than *Srrm4* +/+ littermates. This is associated with a significant decrease in microexon inclusion in the CNS and with multiple autistic-like features, including altered social behaviors, altered synaptic density, and signaling. These results provide evidence that misregulation of human *SRRM4* is causally linked to a substantial fraction of autism cases.

Mouse Srrm4 protein has been found to stimulate the inclusion of microexons by binding to RNA sequences found upstream from microexons. From this position, Srrm4 is able to stimulate snRNP U1 association with the microexon $5'$ splice site in much the same way that SR-proteins bound to exonic splicing enhancers at the $3'$ end of an exon stimulate snRNP U1 association with $5'$ splice sites in exons

of typical length (see Figure 9-16). Once U1 snRNP is associated with the microexon 5′ splice site, it can interact with U2 snRNP associated with the branch point preceding the next 3′ splice site in the pre-mRNA and participate in a splicing reaction that joins the microexon to the downstream exon.

Myelodysplastic syndromes (MDS) are a group of blood cell diseases characterized by deregulated production of dysplastic (abnormal) myelocytes (phagocytic white blood cells). A high percentage of MDS patients progress to acute myeloid leukemia (AML), which is terminal if not controlled. Remarkably, sequencing of all exons (the exome) from MDS patients revealed that mutations in genes encoding a few specific RNA splicing factors occur in ∼60–70 percent of all MDS patients. The vast majority of these mutations occur in genes for the splicing factors U2AF35, SRSF2, ZRSR2, or SF3B1 (Figure 9-22). U2AF35 is the small subunit of the heterodimeric U2AF splicing factor required for association of the U2 snRNP with the branch-point A near the 3′ end of an intron (Figure 9-13). SRSF2 and ZRSR2 are SR proteins that associate with exonic splicing enhancers in many genes. SF3B1 is a protein component of human U2 snRNP. Specific mutations in other splicing factors (U2AF65, SF1, SF3A1 and PRPF40B) also occur in MDS patients, but less frequently. U2AF65 is the large subunit of U2AF that associates with the pyrimidine tract just upstream of the 3′ splice site. SF1 is required along with U2AF for association of U2 snRNP with the branchpoint A. SF3A1 is another protein component

of human U2 snRNP. PRP40B is an essential splicing factor, but its precise function is not yet understood.

FIGURE 9-22 Specific amino acid changes in some proteins required for U2 snRNP binding to the branch-point A are associated with myelodysplastic syndrome and some leukemias. Spliceosome components mutated in myelodysplasic syndromes, related diseases causing reduced cell replication and abnormal development of myelocytes (phagocytic white blood cells). RNA splicing is initiated by the recruitment of U1 snRNP to a $5'$ splice site. SF1 binds the branch-point sequence, and the larger subunit of the U2 auxiliary factor (U2AF65) binds the downstream polypyrimidine tract. The smaller subunit of U2AF (U2AF35) binds to the AG dinucleotide of the $3'$ splice site. U2 snRNP association with the branch-point A also requires two protein splicing factors, SF3A1 and SF3B1. U2AF interactions with an SR-protein bound near the $5'$ end of the downstream exon are also required (see Figure 9-15). SRSF2 and ZRSR2 are SR-proteins that fulfill this function at a large number of $3'$ splice sites. Specific amino acid changes in one of these splicing factors indicated by a lightning bolt is found in the abnormal myelocytes in 60–70 percent of patients with myelodysplastic syndrome. These mutations lead to abnormal inclusion of alternatively spliced exons and introns in a large number of pre-mRNAs. The mutations are lethal when homozygous, but somehow interfere with normal

replication and development when half of the splicing factors have these specific amino acid changes in heterozygous cells. See text.

[Data from K. Yoshida et al., 2011, *Nature* **478**:64.]

Only one of these mutations in a splicing factor gene is observed in the abnormal myeloctyes from any one MDS patient, and the MDS cells always retain a wild-type allele of the mutant gene. That is, the myelodysplastic cells are always heterozygous for the splicing factor mutation. *Most remarkable of all: the same specific mutations recur in different patients.* For example, all MDS-associated mutations in SRSF2 change proline 95 into another amino acid, either histidine, leucine, or arginine. MDS-associated mutations in the small subunit of U2AF, which interacts with the AG at the 3′ end of most introns, either change serine 34 to a phenylalanine or a tyrosine, or change glutamine 157 to an arginine or a proline.

Genetic techniques described in Chapter 6 permitted researchers to substitute MDS-associated mutations for the wild-type splicing factor genes in cultured cells. Cells with homozygous MDS-associated mutations were not viable, indicating that co-expression of the wild-type splicing factor is essential. This is presumably to generate a sufficient number of normally spliced mRNAs for the heterozygous cells to survive. Analysis of RNA splicing in the heterozygous cells showed global abnormalities, as in the abnormal myeloid cells from MDS-patients. The very specific mutations recovered from MDS patients appear to generate a change of

splicing factor function rather than loss of function. For example, loss of SRSF2 results in failure of cassette exon splicing (Figure 9-22), while expression of MDS-associated SRSF2 mutants result in a change in cassette exon splicing in a sequence-specific manner based on the sequence of exonic splicing enhancer (ESE) motifs present in the abnormally spliced exon. In contrast, mutations in U2AF1, which interacts with the pyrimidine tract upstream from the 3′ splice site, alter splicing by promoting the recognition of abnormal 3′ splice sites. Mutations in SF3B1 promote usage of cryptic 3′ splice sites.

How these abnormalities in pre-mRNA splicing influence the phenotype of myelodysplastic cells is not known. In particular, it is not known if the abnormal phenotype is due to (1) expression of one or a few abnormally spliced mRNAs, influencing the function of one or a small number of proteins that regulate myeloid blood cell replication and differentiation, or (2) whether the phenotype results from the pleiotropic effects of abnormal expression of a large number of protein isoforms. ■

Self-Splicing Group II Introns Provide Clues to the Evolution of snRNAs

Under certain nonphysiological in vitro conditions, pure preparations of some RNA transcripts slowly splice out introns in

the absence of any protein. This observation led to the recognition that some introns are *self-splicing*. Two types of self-splicing introns have been discovered: **group I introns**, present in nuclear rRNA genes of protozoans, and **group II introns**, present in protein-coding genes and some rRNA and tRNA genes in mitochondria and chloroplasts of plants and fungi. Discovery of the catalytic activity of self-splicing introns revolutionized concepts about the functions of RNA. As discussed in Chapter 4, RNA is now known to catalyze peptide-bond formation during protein synthesis in ribosomes. Here we discuss the probable role of group II introns, now found only in mitochondrial and chloroplast DNA, in the evolution of snRNAs; the functioning of group I introns is considered in the later section on rRNA processing.

Even though their precise sequences are not highly conserved, all group II introns fold into a conserved, complex secondary structure containing numerous stem loops (Figure 9-23a). Self-splicing by a group II intron occurs via two transesterification reactions, involving intermediates and products analogous to those found in nuclear pre-mRNA splicing. The mechanistic similarities between group II intron self-splicing and spliceosomal splicing led to the hypothesis that snRNAs function analogously to the stem loops in the secondary structure of group II introns. According to this hypothesis, snRNAs interact with 5′ and 3′ splice sites of pre-mRNAs and with each other to produce a three-dimensional RNA structure

functionally analogous to that of group II self-splicing introns (Figure 9-23b).

FIGURE 9-23 Comparison of group II self-splicing introns and the spliceosome. The schematic diagrams compare the secondary structures of (a) group II self-splicing introns and (b) U snRNAs present in the spliceosome. The first transesterification reaction is indicated by light green arrows; the second reaction, by blue arrows. The branch-point A is boldfaced. The similarity in these structures suggests that the spliceosomal snRNAs evolved from group II introns, with the trans-acting snRNAs being functionally analogous to the corresponding domains in group II introns. The colored bars flanking the introns in (a) and (b) represent exons. See P. A. Sharp, 1991, *Science* **254**:663.

An extension of this hypothesis is that introns in ancient pre-mRNAs evolved from group II self-splicing introns through the progressive loss of internal RNA structures, which concurrently evolved into trans-acting snRNAs that perform the same functions. Support for this type of evolutionary model comes from experiments with group II intron mutants in which domain V and part of domain I are

deleted (Figure 9-23a). RNA transcripts containing such mutant introns are defective in self-splicing, but when RNA molecules equivalent to the deleted regions are added to the in vitro reaction, self-splicing occurs. This finding demonstrates that these domains in group II introns can be trans-acting, like snRNAs.

Further evidence that spliceosomal splicing evolved from group II introns comes from recent cryo-EM structures of group II introns showing that the RNA interactions that occur during group II intron splicing are very similar to the interactions at the spliceosome active site (see Figure 9-14b, c). Although group II introns can self-splice in vitro at elevated temperatures and Mg^{2+} concentrations, under in vivo conditions proteins called *maturases,* which bind to group II intron RNA, are required for rapid splicing. Maturases are thought to stabilize the precise three-dimensional interactions of the intron RNA required to catalyze the two splicing transesterification reactions. By analogy, we can now see from the cryo-EM structures of catalytically active spliceosomes (see Figure 9-11) that proteins associated with spliceosomes also stabilize the precise geometry of snRNAs and intron nucleotides required to catalyze pre-mRNA splicing.

The evolution of snRNAs may have been an important step in the rapid evolution of multicellular eukaryotes. As internal intron sequences were lost and their functions in RNA splicing supplanted by trans-acting snRNAs, the remaining intron sequences would be

free to diverge. This in turn likely facilitated the evolution of new genes through **exon shuffling** since there are few constraints on the sequence of new introns generated in the process (see Figures 7-18 and 7-19). It also permitted the increase in protein diversity that results from alternative RNA splicing and an additional level of gene control resulting from regulation of alternative RNA splicing.

Nuclear Exonucleases and the Exosome Degrade RNA That Is Processed out of Pre-mRNAs

Because the human genome contains long introns, only ~5 percent of the nucleotides that are polymerized by RNA polymerase II during transcription are retained in mature, processed mRNAs. Although this process appears inefficient, it probably evolved in multicellular organisms because the process of exon shuffling facilitated the evolution of new genes in organisms with long introns (Chapter 7). The introns that are spliced out and the region downstream from the cleavage and polyadenylation site are degraded by nuclear exoribonucleases that hydrolyze one base at a time from either the 5′ or 3′ end of an RNA strand.

As mentioned earlier, the 2′,5′-phosphodiester bond in excised introns (see Figure 9-13, ILS) is hydrolyzed by a debranching

enzyme, yielding a linear molecule with unprotected ends that can be attacked by exonucleases.

The predominant nuclear decay pathway for RNAs removed from pre-mRNAs by RNA splicing, and the transcribed RNA downstream from a cleavage/polyadenylation site, is $3' \rightarrow 5'$ hydrolysis by a large protein complex called the **exosome** (Figure 9-24). The exosome consists of a nine-subunit barrel referred to as *Exo-9*, comprised of nine similar polypeptides (gray in Figure 9-24). Although these have sequences homologous to bacterial RNA phosphorylases, the Exo-9 barrel has no ribonuclease activity. Rather, it forms a channel through which the RNA substrate is threaded $3'$ end first to finally reach the tenth subunit in the exosome, RRP44, which has the only ribonuclease activity of any subunit of the complex. The major site of RNA digestion is in the exonuclease active site at the end of the channel (Figure 9-24b, marked "Exo.") Since this active site is within the exosome, RNAs outside of the exosome are protected from digestion by the highly active RRP44 exonuclease. The long channel through the large exosome is thought to hold the RNA in optimal conformation for removal of one nucleotide at a time by the rapid exonuclease activity of the complex, without releasing the substrate RNA. This results in what is known as *processive* degradation; the RNA substrate is digested completely (to a tetranucleotide) without being released from the enzyme.

FIGURE 9-24 Structure of the exosome. (a) Structure of the 420 kDa exosome core complex, termed *Exo 10*. It consists of the catalytically inactive Exo 9 complex composed of nine closely related subunits (gray) and the S1 and KH ring (orange). The Exo 9 complex associates with RRP44 (violet), which contains sites of endonuclease (endo) and exonuclease (exo) activity. (b) Schematic representation showing the multisubunit exosome lid, which includes RNA helicases that push RNA substrates through a narrow channel in the lid (blue) that continues into the Exo 10 complex until the 3′ end of the substrate RNA reaches the processive catalytic exonuclease site in RRP44.

[Data from D. Makino, F. Halbach, and E. Conti, 2013, *Nat. Rev. Mol. Cell Biol.* **14**:655.]

In addition to an exonuclease site, RRP44 has an endonuclease site on its surface. This is thought to be utilized when RNA degradation

at the RRP44 exonuclease site is inhibited because of a highly stable RNA structure or chemical damage such as oxidation at the 3′ end of the RNA. In this case, the RRP44 endonuclease site can cleave the substrate RNA 5′ to the block to exonuclease digestion when the blocked substrate RNA diffuses out of the exosome channel. This generates a new 3′ end susceptible to rapid digestion that can be threaded into the exosome, resulting in complete digestion of the RNA.

Since the exonuclease active site is located at the end of a long tunnel in the exosome with dimensions just adequate to accommodate an extended RNA chain, the highly active enzymatic activity does not have access to other nuclear or cytoplasmic RNAs. Rather, substrates must be recognized and loaded into the pore at the top of the exosome before RNA helicases in the lid push the 3′ end of the RNA down the channel until it reaches the exonuclease active site in RRP44 (Figure 9-24b). This regulatory lid on nuclear exosomes is called the *TRAMP complex* and contains the RNA helicase, *Mtr4*. Exosomes in the cytoplasm are associated with a regulatory lid called the *SKI complex* containing the Ski2 RNA helicase. Note that basic design principles of the exosome are similar to those of the major protein degrading multiprotein complex in eukaryotic cells, the proteasome (see Figure 3-32). In both degradative complexes, degradation takes place inside a protein barrel that excludes other potential cellular substrates. The selection of substrates to be rapidly degraded is made by proteins in

a regulatory cap structure that binds one end of the substrate polymer and then, using energy from ATP hydrolysis, pushes it into the digestive cavity as an extended polymer highly susceptible to the degradative enzymes.

In addition to degrading introns, nuclear exosomes appear to degrade pre-mRNAs that have not been properly spliced or polyadenylated, thus providing a quality-control mechanism. It is not yet clear how the exosome recognizes improperly processed pre-mRNAs. But in yeast cells with temperature-sensitive mutant poly(A) polymerase (see Figure 9-15), pre-mRNAs are retained at their sites of transcription in the nucleus at the nonpermissive temperature. These abnormally processed pre-mRNAs are released in cells with a second mutation in a subunit of the exosome found only in nuclear and not in cytoplasmic exosomes (EXOSC10; 100 kD in humans). Also, exosomes are found concentrated at sites of transcription in *Drosophila* polytene chromosomes, where they are associated with RNA polymerase II elongation factors. These results suggest that the exosome participates in an as yet poorly understood quality-control mechanism that recognizes aberrantly processed pre-mRNAs, preventing their export to the cytoplasm and ultimately leading to their degradation.

To avoid being degraded by nuclear exonucleases, nascent transcripts, pre-mRNA processing intermediates, and mature mRNAs in the nucleus must have their ends protected. As discussed

above, the 5′ end of a nascent transcript is protected by addition of the 5′ cap structure as soon as the 5′ end emerges from the polymerase. The 5′ cap is protected because it is bound by a *nuclear cap-binding complex,* which protects it from 5′ exonucleases and also functions in export of mRNA to the cytoplasm. The 3′ end of a nascent transcript lies within the RNA polymerase and thus is inaccessible to exonucleases (see Figure 8-9b). As discussed previously, the free 3′ end generated by cleavage of a pre-mRNA downstream from the poly(A) signal is rapidly polyadenylated by the poly(A) polymerase in a 900 kDa cleavage and polyadenylation complex, and the resulting poly(A) tail is bound by PABPN1 (see Figure 9-15). This tight coupling of cleavage and polyadenylation protects the 3′ end from exonuclease attack.

RNA Processing Solves the Problem of Pervasive Transcription of the Genome in Mammalian Cells

As discussed in Chapter 8, analysis of the location of transcribing RNA polymerase II in metazoan cells revealed the surprising result that the polymerases transcribe in both the downstream direction into coding regions and in the upstream direction away from coding regions at nearly equal frequency from most promoters. This finding was also confirmed by deep sequencing of small RNAs isolated from mammalian cells that revealed low levels of short,

capped RNAs transcribed from both the sense and antisense strands at CpG-island promoters ($\sim$70 percent of mammalian promoters). Indeed, deep sequencing of all cellular RNAs showed that both strands of nearly the entire genome are transcribed, although much of this RNA is present at extremely low concentrations of less than one molecule per cell. This raised the question of how the cell deals with such **pervasive transcription** of the genome.

Sequence analysis of these low-abundance, short RNAs indicates that they are likely prevented from reaching high concentrations by RNA processing and nuclear surveillance of abnormally processed RNAs. Sequencing of RNAs from several cell types revealed that the antisense RNAs have a higher frequency of AAUAAA polyadenylation site sequences than transcripts transcribed in the sense direction into gene coding regions. This is probably because the high AT composition of mammalian DNA ($\sim$60 percent in humans) results in occasional transcription of AAUAAA in antisense transcripts ($\sim 0.6^6 = 4.7$ percent of all six base sequences with an average of 60 percent AT). However, AAUAAA sequences in protein-coding genes occur at much lower frequency because the genes have evolved to have one or a small number of poly(A) sites. Consequently, the enrichment of poly(A) sites in antisense transcripts leads to cleavage of most antisense transcripts within a few kb of their transcription start sites by cleavage/polyadenylation factors, followed by termination of transcription. Most cleaved antisense transcripts are degraded by nuclear exosomes; evidence

for this comes from experiments in which temperature-sensitive mutations in exosome subunits cause a rapid increase in short antisense promoter-proximal RNAs when the mutant cells are shifted to the nonpermissive temperature. As a result, even though a large number of RNA polymerase II molecules transcribe in the "wrong" direction, most of the transcripts generated are degraded before they reach a length of a few kb.

RNA Editing Alters the Sequences of Some Pre-mRNAs

In the mid-1980s, sequencing of numerous cDNA clones and corresponding genomic DNAs from multiple organisms led to the unexpected discovery of another type of pre-mRNA processing. In this type of processing, called **RNA editing**, the sequence of a pre-mRNA is altered; as a result, the sequence of the corresponding mature mRNA differs from the exons encoding it in genomic DNA.

RNA editing is widespread in the mitochondria of protozoans and plants and also in chloroplasts. In the mitochondria of certain pathogenic trypanosomes, more than half the sequence of some mRNAs is altered from the sequence of the corresponding primary transcripts. Additions and deletions of specific numbers of U's follow templates provided by base-paired short "guide" RNAs. These RNAs are encoded by thousands of mini-mitochondrial DNA circles

catenated to many fewer large mitochondrial DNA molecules. The reason for this baroque mechanism for encoding mitochondrial proteins in such protozoans is not clear. But this system does represent a potential target for drugs to inhibit the complex processing enzymes essential to the microbe that do not exist in the cells of their human or other vertebrate hosts.

In multicellular eukaryotes, RNA editing is much rarer, and, thus far, only single-base changes have been observed in mammals. Such minor editing, however, turns out to have significant functional consequences in some cases. An important example of RNA editing in mammals involves the *apoB* gene. This gene encodes two alternative forms of a serum protein central to the uptake and transport of cholesterol. Consequently, it is important in the pathogenic processes that lead to *atherosclerosis,* the arterial disease that is the major cause of death in the developed world. The *apoB* gene expresses both the serum protein apolipoprotein B-100 (apoB-100) in hepatocytes, the major cell type in the liver, and apoB-48, expressed in intestinal epithelial cells. The ~240-kDa apoB-48 corresponds to the N-terminal region of the ~500-kDa apoB-100. As we detail in Chapter 14, both apoB proteins are components of large lipoprotein complexes that transport lipids in the serum. However, only low-density lipoprotein (LDL) complexes, which contain apoB-100 on their surface, deliver cholesterol to body tissues by binding to the LDL receptor present on all cells.

The cell-type-specific expression of the two forms of apoB results from editing of *apoB* pre-mRNA so as to change the nucleotide at position 6666 in the sequence from a C to a U. This alteration, which occurs only in intestinal cells, converts a CAA codon for glutamine to a UAA stop codon, leading to synthesis of the shorter apoB-48 (Figure 9-25). Studies with the partially purified enzyme that performs the post-transcriptional deamination of C_{6666} to U shows that it can recognize and edit an RNA as short as 26 nucleotides with the sequence surrounding C_{6666} in the *apoB* primary transcript, but it does not deaminate C's in RNAs with other sequences.

FIGURE 9-25 RNA editing of apoB pre-mRNA. The apoB mRNA produced in the liver has the same sequence as the exons in the primary transcript. This mRNA is translated into apoB-100, which has two functional domains: an N-terminal domain (green) that associates with lipids and a C-terminal domain (orange) that binds to LDL receptors on cell membranes. In the apo-B mRNA produced in the intestine, the CAA codon in exon 26 is edited to a UAA stop codon. As a result, intestinal cells produce apoB-48, which corresponds to the N-terminal domain of apoB-100. See P. Hodges and J. Scott, 1992, *Trends Biochem. Sci.* **17**:77.

KEY CONCEPTS OF SECTION 9.2

Regulation of Pre-mRNA Processing

- Because of alternative splicing of primary transcripts, the use of alternative promoters, and cleavage at different poly(A) sites, different mRNAs may be expressed from the same gene in different cell types or at different developmental stages (see Figure 9-18). This vastly expands the number of distinct proteins encoded in the genomes of multicellular animals and plants compared to eukaryotes that exhibit little alternative RNA splicing such as *Saccharomyces cerevisiae.*
- SR proteins that bind to exonic splicing enhancer sequences present in some exons are critical for defining the splice sites of these exons in the large pre-mRNAs of vertebrates. A network of interactions between SR proteins, snRNPs, and splicing factors forms a cross-exon recognition complex over the short vertebrate exon that specifies correct localization of splice sites (see Figure 9-16).
- Alternative splicing can be regulated by RNA-binding proteins that bind to specific sequences near regulated splice sites. Splicing repressors may sterically block the binding of splicing factors to specific sites in pre-mRNAs or inhibit their function. Splicing activators enhance splicing by interacting with splicing factors, thus promoting their association with a regulated splice site. The RNA sequences bound by splicing repressors are called *intronic* or *exonic splicing silencers*, depending on their location in an intron or exon. RNA sequences bound by splicing activators are called *intronic* or *exonic splicing enhancers*.
- Excised introns and RNA downstream from the cleavage/polyadenylation site are degraded primarily by exosomes, multiprotein complexes that contain an internal $3' \rightarrow 5'$ exonuclease. Exosomes also degrade improperly processed pre-mRNAs.
- Multiple human genetic diseases result from abnormal splicing. A base pair change in a pre-mRNA can create a consensus $5'$ or $3'$ splice site sequence, leading to splicing of an abnormal mRNA that does not encode a functional protein. A base pair change in an exonic splicing enhancer can cause skipping of the exon. Mutations causing specific amino acid changes in a subset of splicing factors cause myelodysplastic syndromes that are precursors to acute myeloid leukemia (AML).
- Group II self-splicing introns in mitochondria and chloroplasts of protozoa, plants, and fungi may represent evolutionary precursors of snRNAs and their ability to act in trans at the short splice site sequences of nuclear pre-mRNAs.
- In RNA editing, the nucleotide sequence of a pre-mRNA is altered in the nucleus. In vertebrates, this process is relatively rare, and only single-base C to U changes have been observed, but those changes can have important consequences by altering the amino acid encoded by an edited codon (see Figure 9-25). In pathogenic trypanosome mitochondria (called *kinetoplasts*) RNA editing using separately transcribed guide

RNAs leads to insertions and base changes comprising more than half of the length of some kinetoplast mRNAs.

9.3 Transport of mRNA Across the Nuclear Envelope

Before an mRNA can be translated into its encoded protein, it must be exported out of the nucleus into the cytoplasm. The nucleus is separated from the cytoplasm by the **nuclear envelope**, a double membrane that is continuous with the endoplasmic reticulum (ER) (see Figure 1-16). Like the plasma membrane surrounding cells, the inner and outer nuclear membranes consist of water-impermeable phospholipid bilayers and multiple associated proteins. Fully processed mRNAs in the nucleus remain bound by hnRNP proteins in complexes referred to as *nuclear mRNPs.* mRNPs and other macromolecules including tRNAs and ribosomal subunits traverse the nuclear envelope through *nuclear pores.* This section will focus on the export of mRNPs through the nuclear pore and the mechanisms that allow some level of regulation of this step. Transport of other cargoes across the nuclear pore is discussed in Chapter 13.

Embedded in the nuclear envelope, **nuclear pore complexes (NPCs)** are cylindrical in shape with a diameter of ~30 nm (see Figure 13-32). Proteins and RNPs larger than ~40–60 kDa must be selectively transported across NPCs with the assistance of soluble transporter proteins. These nuclear transporters bind cargo to be transported across an NPC and also interact reversibly with short hydrophobic FG-repeat regions in random coil polypeptides extending from the

NPC walls into the central channel. As a consequence of these reversible interactions with FG-domains, the transporter and its stably bound cargo can be passed from FG-domain to FG-domain, allowing the complex of transporter and cargo to diffuse down a concentration gradient: the concentration of the transporter-cargo protein complex is high in the nucleus where the complexes form, and low in the cytoplasm where the transporter-cargo complexes dissociate.

Most types of mRNPs are transported through the NPC by the **mRNP exporter**, a heterodimer consisting of a large subunit, called *n*uclear e*x*port *f*actor *1* (NXF1), and a small subunit, *n*uclear e*x*port *t*ransporter *1* (NXT1). NXF1 binds nuclear mRNPs through associations with both RNA and other proteins in the mRNP complex. One of the most important of these is REF (*R*NA *e*xport *f*actor), a component of the exon-junction complexes discussed earlier, which is bound approximately 20 nucleotides 5′ to each exon-exon junction. The NXF1/NXT1 mRNP exporter also associates with SR proteins bound to exonic splicing enhancers. Thus SR proteins associated with exons function to direct both the splicing of pre-mRNAs and the export of fully processed mRNAs through NPCs to the cytoplasm. mRNPs are probably bound along their length by multiple NXF1/NXT1 mRNP exporters, which interact with the FG-domains of FG-nucleoporins to facilitate export of mRNPs through the NPC central channel.

Protein filaments extend from the NPC core scaffold into the nucleoplasm, forming a *nuclear basket* (see Figure 13-32b). Protein filaments also extend into the cytoplasm. These filaments assist in mRNP export. Gle2, an adapter protein that reversibly binds both NXF1 and a protein in the nuclear basket, brings nuclear mRNPs to the pore in preparation for export. A protein in the cytoplasmic filaments of the NPC binds an RNA helicase (Dbp5) that functions in the dissociation of NXF1/NXT1 and other hnRNP proteins from the mRNP as it reaches the cytoplasm.

In a process called *mRNP remodeling,* the proteins associated with an mRNA in the nuclear mRNP complex are exchanged for a different set of proteins as the mRNP is transported through the NPC (Figure 9-26). Some nuclear mRNP proteins, like hnRNPC (see Figure 9-5) dissociate early in transport, remaining in the nucleus to bind to newly synthesized nascent pre-mRNA. Other nuclear mRNP proteins remain with the mRNP complex as it traverses the pore and do not dissociate from the mRNP until the complex reaches the cytoplasm, like hnRNPA1 (see Figure 9-5). Proteins in this category include the NXF1/NXT1 mRNP exporter, cap-binding complex (CBC) bound to the 5′ cap, and PABPN1 bound to the poly(A) tail. They dissociate from the mRNP on the cytoplasmic side of the NPC through the action of the Dbp5 RNA helicase that associates with cytoplasmic NPC filaments, as discussed above. These proteins are then imported back into the nucleus where they can function in the export of another mRNP. In the cytoplasm, the cap-binding

translation initiation factor eIF4E replaces CBC bound to the 5′ cap of nuclear mRNPs. In humans, the nuclear poly(A)-binding protein PABPN1 is replaced with the cytoplasmic poly(A)-binding proteins PABPC1, PABPC2, or PABPC3. Only a single PABP is found in budding yeast, in both the nucleus and the cytoplasm.

FIGURE 9-26 Remodeling of mRNPs during nuclear export. Some mRNP proteins (purple) dissociate from nuclear mRNP complexes before export through an NPC. Some (yellow) are exported through the NPC associated with the mRNP but

dissociate in the cytoplasm and are shuttled back into the nucleus through an NPC. In the cytoplasm, translation initiation factor eIF4E replaces CBC bound to the 5′ cap and PABPCI, 2, or 3 replaces PABPNI.

SR Proteins Mediate Nuclear Export of mRNA

Studies of *S. cerevisiae* indicate that the direction of mRNP export from the nucleus into the cytoplasm is controlled by phosphorylation and dephosphorylation of mRNP adapter proteins such as REF that assist in the binding of the NXF1/NXT1 exporter to mRNPs. For example, a yeast SR protein (Npl3) functions as an adapter protein that promotes the binding of the yeast mRNP exporter (Figure 9-27). The SR protein initially binds to nascent pre-mRNAs in its phosphorylated form. When 3′ cleavage and polyadenylation are completed, the adapter protein is dephosphorylated by a specific nuclear protein phosphatase essential for mRNP export. Only the dephosphorylated adapter protein can bind the mRNP exporter, thereby coupling mRNP export to correct polyadenylation. This is one form of mRNA *quality control*. If the nascent mRNP is not correctly processed, it is not recognized by the phosphatase that dephosphorylates Npl3. Consequently, it is not bound by the mRNA exporter and not exported from the nucleus. Instead, it is degraded by exosomes, the multiprotein

complexes that degrade unprotected RNAs in the nucleus and cytoplasm (see Figure 9-24).

FIGURE 9-27 Reversible phosphorylation of mRNP proteins controls the direction of mRNP nuclear export. Step 1: The yeast SR protein Npl3 binds nascent pre-mRNAs in its phosphorylated form. Step 2: When polyadenylation has occurred successfully, the Glc7 nuclear phosphatase essential for mRNP export dephosphorylates Npl3, promoting the binding of the yeast mRNP exporter, NXF1/NXT1. Step 3: The mRNP exporter allows diffusion of the mRNP complex through the central channel of the nuclear pore complex (NPC). Steps 4 and 5: The cytoplasmic protein kinase Sky1 phosphorylates Npl3 in the cytoplasm, causing dissociation of the mRNP exporter and phosphorylated Npl3, probably through the action of an RNA helicase associated with NPC cytoplasmic filaments. Step 6: The mRNA transporter and phosphorylated Npl3 are transported back into the nucleus through NPCs. Step 7: Transported mRNA is available for translation in the cytoplasm. See

E. Izaurralde, 2004, *Nat. Struct. Mol. Biol.* **11**:210–212. Data from W. Gilbert and C. Guthrie, 2004, *Mol. Cell* **13**:201–212.

Following export to the cytoplasm, the Npl3 SR protein is phosphorylated by a specific protein kinase localized in the cytoplasm. This causes it to dissociate from the mRNP, along with the mRNP exporter. In this way, dephosphorylation of adapter mRNP proteins in the nucleus once RNA processing is complete, and their phosphorylation and resulting dissociation in the cytoplasm drives mRNP nuclear export. This results in a higher concentration of mRNP exporter–mRNP complexes in the nucleus, where they form, and a lower concentration of these complexes in the cytoplasm, where they dissociate. Consequently, the direction of mRNP export may be driven by simple diffusion down a concentration gradient of the transport-competent mRNP exporter–mRNP complex across the NPC, from high concentration in the nucleus to low concentration in the cytoplasm.

Nuclear Export of Balbiani Ring mRNPs

The larval salivary glands of the insect *Chironomous tentans* provide a good model system where assembly of an mRNP and its transport across an NPC can be visualized by electron microscopy. In these larvae, genes in large chromosomal puffs called *Balbiani rings* are abundantly transcribed into nascent pre-mRNAs that associate with hnRNP proteins and are processed into coiled mRNPs with a final

mRNA length of ~75 kb (Figure 9-28a, b). These giant mRNAs encode large glue proteins that adhere the developing larvae to a leaf. After processing of the pre-mRNA in Balbiani ring hnRNPs, the resulting mRNPs move through nuclear pores to the cytoplasm. Electron micrographs of sections of these cells show mRNPs that appear to uncoil during their passage through nuclear pores and then bind to ribosomes as they enter the cytoplasm. This uncoiling is probably a consequence of the remodeling of mRNPs as the result of phosphorylation of mRNP proteins by cytoplasmic kinases and the action of the RNA helicase associated with NPC cytoplasmic filaments, as discussed in the previous section. The observation that mRNPs become associated with ribosomes during transport indicates that the 5′ end leads the way through the nuclear pore complex. Detailed electron microscopic studies of the transport of Balbiani ring mRNPs through nuclear pore complexes led to the model depicted in Figure 9-28c.

FIGURE 9-28 Formation of heterogeneous ribonucleoprotein particles (hnRNPs) and export of mRNPs through NPCs in *Chironomus tentans* salivary gland cells during metamorphosis. (a) Model of a single chromatin transcription loop and assembly of Balbiani ring (BR) mRNP in *Chironomus tentans*. Nascent RNA transcripts produced from the template DNA rapidly associate with proteins, forming hnRNPs. The gradual increase in size of the hnRNPs reflects the increasing length of RNA transcripts at greater distances from the transcription start site. The model was reconstructed from electron micrographs of serial thin sections of salivary gland cells. (b) Model of the morphology of the BR hnRNP as it grows in length during its transcription. Following processing and cleavage/polyadenylation of the pre-mRNA, the resulting ribonucleoprotein particle, referred to as an *mRNP*, appeared like a microscopic croissant by EM. (c) Model for the transport of BR mRNPs through the nuclear pore complex (NPC) based on electron microscopic studies. Note that the curved mRNPs appear to uncoil as they pass through nuclear pores. As the mRNA enters the cytoplasm, it rapidly associates with ribosomes, indicating that the 5′ end passes through the NPC first. Parts (b) and (c) see B. Daneholt, 1997, *Cell* **88**:585. See also B. Daneholt, 2001, *Proc. Nat'l. Acad. Sci. USA* **98**:7012.

Pre-mRNAs Associated with Spliceosomes Are Not Exported from the Nucleus

It is critical that only fully processed, mature mRNAs be exported from the nucleus because translation of incompletely processed pre-mRNAs containing introns would produce defective proteins that might interfere with normal cellular functions. To prevent this, pre-mRNAs associated with snRNPs in spliceosomes are usually prevented from being transported to the cytoplasm.

In one type of experiment demonstrating this restriction, levels of cytoplasmic and nuclear RNAs were determined for RNAs expressed from a derivative of the rabbit β–globin gene containing only the second intron (see Figure 9-2). This modified β–globin gene expressed high levels of fully processed β–globin mRNA in the cytoplasm and only low levels of the unspliced hnRNA in the nucleus, presumably the initial transcript before being subjected to RNA splicing and export to the cytoplasm. However, when the invariant GT at the 5′ end of the globin intron, *or* the invariant AG at the 3′ end of the intron were mutated, splicing of this pre-mRNA was

blocked, and it was retained in the nucleus. Remarkably, when both the 5′ and 3′ splice sites in the pre-mRNA were mutated, splicing did not occur, as expected, but the unspliced mutant β–globin RNA was exported to the cytoplasm. Further studies revealed that transcripts with only one intact splice site were bound by snRNPs to form intermediates in spliceosome assembly that could not complete the splicing process because of the absence of the second splice site. However, RNA expressed from the mutant gene in which both the 5′- and 3′-splice site–invariant bases were mutated was not assembled into spliceosome assembly intermediates with U1 or U2 snRNPs, but as mentioned above, these RNAs were exported. Further studies in yeast have shown that a nuclear protein that associates with a protein in the NPC nuclear basket is required to retain pre-mRNAs in the nucleus that are associated with spliceosome assembly intermediates. If the gene encoding this protein or the nuclear pore basket protein to which it binds is deleted, unspliced pre-mRNAs are exported. Thus intermediates in spliceosome assembly are actively prevented from being exported to the cytoplasm. Another important observation made in these experiments was that the mutant hnRNAs retaining only one 5′ or 3′ splice site that are retained in the nucleus do not build up to high concentration. Consequently, some mechanism exists that causes degradation of the hnRNAs that cannot be spliced. Understanding how such RNAs are selected for degradation is a goal of current research.

Many cases of thalassemia, an inherited disease that results in abnormally low levels of adult globin proteins, result from mutations in adult globin-gene splice sites that decrease the efficiency of splicing and cause the mutant pre-mRNA to be retained in the nuclei of developing red blood cells in the bone marrow (erythrocyte precursors). The resulting unspliced nuclear globin pre-mRNAs are recognized by mechanisms still being elucidated, and degraded by nuclear exosomes (see Figure 9-24). ■

HIV Rev Protein Regulates the Transport of Unspliced Viral mRNAs

As discussed earlier, transport of fully processed nuclear mRNPs containing mature, functional mRNAs from the nucleus to the cytoplasm entails a complex mechanism that is crucial to gene expression (see Figures 9-26 and 9-27). Regulation of this transport could theoretically provide another means of gene control, although it appears to be relatively rare. The only known examples of regulated mRNA export occur during the cellular response to conditions that cause protein denaturation (e.g., heat shock) or during viral infection when virus-induced alterations in nuclear transport maximize viral replication.

One example of the regulation of mRNP export comes from a protein encoded by human immunodeficiency virus (HIV). A

retrovirus, HIV integrates a DNA copy of its RNA genome into the host-cell DNA (see Figure 5-43). The integrated viral DNA, or provirus, contains a single transcription unit, which is transcribed into a single primary transcript by cellular RNA polymerase II. The HIV transcript can be spliced in alternative ways to yield three classes of mRNAs: a 9-kb unspliced mRNA, ~4-kb mRNAs formed by removal of one intron, and ~2-kb mRNAs formed by removal of two or more introns (Figure 9-29). After their synthesis in the host-cell nucleus, all three classes of HIV mRNAs are transported to the cytoplasm and translated into viral proteins; some of the 9-kb unspliced RNA is used as the viral genome in progeny virions that bud from the cell surface.

FIGURE 9-29 Transport of HIV mRNAs from the nucleus to the cytoplasm. The HIV genome, which contains several coding regions, is transcribed into a single 9-kb primary transcript. Several ~4-kb mRNAs result from alternative splicing out of any one of several introns (dashed lines) and several ~2-kb mRNAs from splicing out of two or more alternative introns. After transport to the cytoplasm, the various RNA species are translated into

different viral proteins. Rev protein, encoded by a 2-kb mRNA, interacts with the Rev-response element (RRE) in the unspliced and singly spliced mRNAs, stimulating their transport to the cytoplasm. See B. R. Cullen and M. H. Malim, 1991, *Trends Biochem. Sci.* **16**:346.

Since the 9-kb and 4-kb HIV mRNAs contain splice sites, they can be viewed as incompletely spliced pre-RNAs. Association of such incompletely spliced mRNAs with snRNPs in spliceosome assembly intermediates normally blocks their export from the nucleus. Thus HIV, as well as other retroviruses, must have some mechanism for overcoming this block, permitting export of the longer viral mRNAs.

Studies with HIV mutants showed that transport of unspliced 9-kb and singly spliced 4-kb viral mRNAs from the nucleus to the cytoplasm requires the virus-encoded Rev protein. Biochemical experiments show that Rev binds to a specific Rev-response element (RRE) present in HIV RNA. Early in an infection, before any Rev protein is synthesized, only the multiply spliced 2-kb mRNAs can be exported. One of these 2-kb mRNAs encodes Rev, which contains a leucine-rich nuclear export signal that interacts with the transporter Exportin 1. After translation and nuclear import of Rev, Rev binds to the RRE sequence in unspliced and singly spliced HIV RNAs. Rev then associates with Exportin 1, resulting in export of the larger unspliced and singly spliced HIV mRNAs through the nuclear pore complex without the assistance of NXF1/NXT1, the major mRNP exporter for cellular mRNPs. In cells infected with HIV mutants lacking the RRE, unspliced and singly spliced viral mRNAs remain

in the nucleus, confirming that the RRE is required for Rev-mediated stimulation of nuclear export.

KEY CONCEPTS OF SECTION 9.3

Transport of mRNA Across the Nuclear Envelope

- Most mRNPs are exported from the nucleus by a heterodimeric mRNP exporter that interacts with the central channel of the nuclear pore complex (NPC).
- The direction of transport (nucleus to cytoplasm) is controlled by phosphorylation of mRNP adaptor proteins. For example, the yeast Npl3 adapter protein enters nuclei only when it is phorphorylated and associates with nascent pre-mRNAs as they are transcribed (see Figure 9-27). When polyadenylation of the pre-mRNA is complete, a nuclear protein phosphatase (Glc7) removes the phosphates from Npl3, allowing the pre-mRNA to interact with the NXF1/NXT1 mRNP exporter, causing export of the pre-mRNP to the cytoplasm. When the mRNP reaches the cytoplasm, the Sky1 protein kinase restricted to the cytoplasm phosphorylates Npl3, causing dissociation of the mRNP transporter, completing delivery of the mRNP to the cytoplasm.
- The mRNP exporter binds to most mRNAs cooperatively with SR proteins bound to exonic splicing enhancers and with REF associated with exon-junction complexes as well as with additional mRNP proteins.
- Pre-mRNAs bound by a spliceosome normally are not exported from the nucleus, ensuring that only fully processed, functional mRNAs reach the cytoplasm for translation.

9.4 Cytoplasmic Mechanisms of Post-Transcriptional Control

Before proceeding, let's quickly review the steps in gene expression at which control is exerted. We saw in the previous chapter that regulation of transcription initiation and transcription elongation in the promoter-proximal region are the initial mechanisms for controlling the expression of genes in the gene expression pathway of DNA → RNA → protein. In preceding sections of this chapter, we learned that the expression of protein isoforms is controlled by regulating alternative RNA splicing and cleavage and polyadenylation at alternative poly(A) sites. Although nuclear export of fully and correctly processed mRNPs to the cytoplasm is rarely regulated, the export of improperly processed or aberrantly remodeled pre-mRNPs is prevented, and such abnormal transcripts are degraded by the exosome. However, retroviruses, including HIV, have evolved mechanisms that permit pre-mRNAs that retain splice sites to be exported and translated.

In this section, we consider other mechanisms of post-transcriptional control that contribute to regulating the expression of many genes. Most of these mechanisms operate in the cytoplasm, controlling the stability or localization of mRNA or its translation into protein.

The Concentration of an mRNA in the Cytoplasm Is Determined by Its Rate of Synthesis and Its Rate of Degradation

The most stable mRNAs encode proteins required in large numbers, such as the ribosomal proteins; these can accumulate to very high copy number per cell. In contrast, highly unstable mRNAs encoding proteins expressed in short bursts — such as cytokines, secreted proteins that regulate the immune response — rarely achieve such high concentrations even when transcribed, processed, and exported from the nucleus at high rates. We begin by discussing the major pathways that degrade mRNAs. Next we discuss two related mechanisms of gene control that provide powerful new techniques for manipulating the expression of specific genes for experimental and therapeutic purposes.

These two mechanisms are controlled by short, ~22-nucleotide, single-stranded RNAs called **microRNAs (miRNAs)** and **short interfering RNAs (siRNAs)**. Both base-pair with specific target mRNAs, causing their rapid degradation (siRNAs) or inhibiting their translation and inducing a slower form of degradation (miRNAs). Approximately 1900 human miRNAs have been characterized. Most of these are expressed in specific cell types at particular times during embryogenesis and after birth. Many miRNAs can target more than one mRNA. Consequently, these mechanisms contribute significantly to the regulation of gene expression. siRNAs, involved

in the process called *RNA interference*, are an important cellular defense against viral infection and excessive transposition by retrotransposons. We also discuss mechanisms that control the overall rate of protein synthesis, and highly specific regulation of the translation and stability of particular mRNAs by proteins that bind them with high specificity. Finally, we discuss mechanisms that control the localization of mRNAs in the cytoplasm of asymmetric cells so that the encoded protein is translated at sites in the cell where it is needed.

Degradation of mRNAs in the Cytoplasm Occurs by Several Mechanisms

The concentration of an mRNA is a function of both its rate of synthesis and its rate of degradation. For this reason, if two genes are transcribed at the same rate, the steady-state concentration of the corresponding mRNA that is more stable will be higher than the concentration of the other. The stability of an mRNA also determines how rapidly the synthesis of the encoded protein can be shut down. For a stable mRNA, synthesis of the encoded protein persists long after transcription of the gene is repressed. Most bacterial mRNAs are unstable, decaying exponentially with a typical half-life of a few minutes. For this reason, a bacterial cell can rapidly adjust the synthesis of proteins to accommodate changes to the

cellular environment. Most cells in multicellular organisms, on the other hand, exist in a fairly constant environment and carry out a specific set of functions over periods of days to months or even the lifetime of the organism (nerve cells, for example). Accordingly, most mRNAs of multicellular eukaryotes have half-lives of many hours.

Some proteins in eukaryotic cells are required only for short periods and must be expressed in bursts. For example, certain signaling molecules called *cytokines*, which are involved in regulating the immune response of mammals, are synthesized and secreted in short bursts (see Chapter 24). Similarly, many of the transcription factors that regulate the onset of the S phase of the cell cycle, such as Fos and Jun, are synthesized for only brief periods (see Chapter 19). Expression of such proteins occurs in short bursts because transcription of their genes can be rapidly turned on and off, and their mRNAs have unusually short half-lives, on the order of 30 minutes or less, so that concentration of the mRNA falls rapidly when its transcription is repressed.

Cytoplasmic mRNAs are degraded by one of the three pathways shown in Figure 9-30. For most mammalian mRNAs, the *deadenylation-dependent pathway* is followed (Figure 9-30a). The length of the poly(A) tail gradually decreases with time through the action of a deadenylating nuclease complex in the cytoplasm. When it is shortened sufficiently, PABPC molecules can no longer bind and

stabilize the interaction of the 5′ cap and translation initiation factors (see Figure 5-36). The exposed cap then is removed by a heterodymeric decapping enzyme (Dcp1/Dcp2), leaving the unprotected mRNA susceptible to degradation by a 5′ → 3′ exonuclease (Xrn1) (Figure 9-30 step **1**). Removal of the poly(A) tail also makes mRNAs susceptible to degradation by cytoplasmic exosomes containing 3′ → 5′ exonuclease activity (Figure 9-30 step **2**). The 5′ → 3′ exonuclease pathway step **1** predominates in yeast, and the 3′ → 5′ exosome pathway step **2** predominates in mammalian cells.

FIGURE 9-30 Pathways for degradation of eukaryotic mRNAs. (a) In the most common pathway of mRNA degradation, the deadenylation-dependent pathway, the poly(A) tail is progressively shortened by a deadenylase complex in the cytoplasm (orange) until it reaches a length of 20 or fewer A residues, at which point the interaction with PABPC1 and the remaining poly(A) is destabilized. This leads to weakened interactions between the 5′ cap and translation initiation factors (see Figures 5-36, step **3**, and Figure 5-39). The

deadenylated mRNA then may either **1** be decapped by the DCP1/DCP2 deadenylation complex and degraded by XRN1, a $5' \rightarrow 3'$ exonuclease, or **2** be degraded by $3' \rightarrow 5'$ exonucleases in cytoplasmic exosomes. (b) Other mRNAs are decapped before they are deadenylated and then degraded by the XRN1 $5' \rightarrow 3'$ exonuclease. (c) Some mRNAs are cleaved internally by an endonuclease and the fragments degraded by a cytoplasmic exosome and the XRN1 exonuclease. See N. L. Garneau, J. Wilusz, and C. J. Wilusz, 2007, *Nat. Rev. Mol. Cell Biol.* **8**:113.

The decapping enzymes and $5' \rightarrow 3'$ exonuclease are concentrated in cytoplasmic **P bodies** (processing bodies), regions of the cytoplasm with unusually high concentrations of RNPs. These regions of highly concentrated proteins are not surrounded by a lipid bilayer membrane. Their formation is dependent on multivalent, low-affinity interactions between simple short repeats of amino acid sequence within intrinsically disordered regions (IDRs) of cytoplasmic RNA-binding proteins associated with some RNAs. These are similar to the transcriptional condensates discussed in Chapter 8 (see Figure 8-38). The process that generates such protein concentrates in both the nucleus and cytoplasm has been called a "liquid-liquid phase separation." This process was first studied for RNA-binding proteins in the cytoplasm that generate P bodies and large cytoplasmic mRNP complexes that are transported to specific regions of the cell by myosin motor proteins that "walk" on actin filaments (see Figure 9-40, and Chapter 17) or by kinesin and dynein motor proteins that walk on microtubules (Chapter 18).

The rate of mRNA deadenylation varies inversely with the frequency of translation initiation for an mRNA: the higher the frequency of

initiation, the slower the rate of deadenylation. This relation probably is due to the reciprocal interactions between translation initiation factors bound at the 5′ cap and PABPC bound to the poly(A) tail. For an mRNA that is translated at a high rate, initiation factors are bound to the cap much of the time, stabilizing the binding of PABPC and thereby protecting the poly(A) tail from deadenylation exonuclease complexes.

AU-Rich Elements

Many short-lived mRNAs in mammalian cells encoding proteins — such as cytokines and transcription factors whose concentrations are changed rapidly — contain multiple, sometimes overlapping copies of the sequence AUUUA in their 3′ untranslated region. These are known as *AU-rich elements*. Specific RNA-binding proteins have been found that both bind to these 3′-AU-rich sequences and also interact with a deadenylating enzyme and with the exosome. This causes rapid deadenylation and subsequent degradation of these mRNAs (Figure 9-30a).

In this mechanism, the rate of mRNA degradation is uncoupled from the frequency of translation. Thus mRNAs containing AU-rich elements can be translated at high frequency yet also be degraded rapidly, allowing the encoded proteins to be expressed in short bursts.

Some mRNAs are degraded primarily by a *deadenylation-independent decapping pathway* (see Figure 9-30b). This is because certain sequences at the 5′ end of an mRNA make the cap sensitive to the decapping enzyme. For these mRNAs, the rate at which they are decapped controls the rate at which they are degraded because once the 5′ cap is removed, the RNA is rapidly hydrolyzed by the $5' \rightarrow 3'$ exonuclease Xrn1.

Finally, as shown in Figure 9-30c, some mRNAs are degraded by an *endonucleolytic pathway* that does not involve decapping or significant deadenylation. One example of this type of pathway is the RNAi pathway discussed below. Each siRNA-RISC complex can degrade multiple targeted RNA molecules. The fragments generated by internal cleavage then are degraded by exonucleases.

MicroRNAs Repress Translation and Induce Degradation of Specific mRNAs

MicroRNAs (miRNAs) were first discovered during analysis of mutations in the *lin-4* and *let-7* genes of the nematode *C. elegans,* which influence development of the organism. Cloning and analysis of wild-type *lin-4* and *let-7* revealed that they do not encode protein but rather RNAs only 21 and 22 nucleotides long, respectively. The RNAs hybridize to the 3′ untranslated regions of specific target mRNAs. For example, the *lin-4* miRNA, which is expressed early in

larval development, hybridizes to the 3′ untranslated regions of both the *lin-14* and *lin-28* mRNAs in the cytoplasm, thereby destabilizing these mRNAs and repressing their translation. Expression of *let-7* miRNA occurs at comparable times during embryogenesis of all bilaterally symmetric animals, including insects and mammals.

miRNA-mediated regulation appears to be widespread in all multicellular plants and animals. In the past few years, small RNAs of 20–26 nucleotides have been isolated, cloned, and sequenced from various tissues of multiple-model organisms. Recent estimates suggest the expression of ~60% of all human genes is regulated by one or more of the 556 well-validated human miRNAs that have been isolated from various tissues. The potential for regulation of multiple mRNAs by one miRNA is high because base pairing between the miRNA and the sequence in the 3′ ends of mRNAs that they regulate need not be perfect (Figure 9-31a). In fact, considerable experimentation with synthetic miRNAs has shown that complementarity between bases two to seven at the 5′ end of an miRNA (called the *seed* sequence) and its target mRNA 3′ untranslated region are most critical for target mRNA selection.

FIGURE 9-31 The extent of base pairing with the miRNA determines the fate of the target RNA. (a) When miRNAs hybridize imperfectly with their target mRNAs, deadenylation is induced and the mRNA is degraded by deadenylation-dependent decay (Figure 9-30a). Nucleotides 2 to 7 of an miRNA (highlighted blue) are the most critical for targeting it to a specific mRNA. The CXCR4 miRNA shown at the bottom is a synthetic oligonucleotide introduced into cells by transfection. (b) miRNAs can also extensively pair to their target mRNAs, causing cleavage of the mRNA at the position indicated by the red arrow, triggering its rapid degradation. See P. D. Zamore and B. Haley, 2005, *Science* **309**:1519.

Most miRNAs are processed from RNA polymerase II transcripts of several hundred to thousands of nucleotides in length called *pri* (for *pri*mary transcript)-miRNAs (Figure 9-32). Pri-miRNAs can contain the sequence of one or more miRNAs. miRNAs are also processed out of some excised introns. Within these long transcripts are sequences that fold into hairpin structures of ~60 nucleotides in length with imperfect base pairing in the stem. A nuclear RNase specific for double-stranded RNA called **Drosha** acts in concert with a nuclear double-stranded RNA-binding protein called *DGCR8* in

humans and cleaves most of the hairpin region out of the long precursor RNA, generating a 60 nucleotide pre-miRNA. Pre-miRNAs are recognized and bound by a specific nuclear export factor, *Exportin5,* which allows the complex to diffuse through the inner channel of the nuclear pore complex. Once in the cytoplasm, a cytoplasmic double-stranded RNA-specific RNase called **Dicer** acts with a cytoplasmic double-stranded RNA-binding protein called *TRBP* in humans (for *T*ar *b*inding *p*rotein) to further process the pre-miRNA into a double-stranded miRNA. The double-stranded miRNA is approximately two turns of an A-form RNA helix in length, with strands 21–23 nucleotides long and with two unpaired 3′ nucleotides at each end.

FIGURE 9-32 miRNA processing. This diagram shows transcription and processing of the miR-1-1 miRNA. The primary miRNA transcript (pri-miRNA) is transcribed by RNA polymerase II. The nuclear double-stranded RNA-specific endoribonuclease Drosha, with its partner double-stranded RNA-binding protein DGCR8, make the initial cleavages in the pri-miRNA, generating a ~70-nucleotide pre-miRNA (step 1) that is exported to the cytoplasm by nuclear transporter Exportin5 (step 2). The pre-miRNA is further processed in the cytoplasm to a double-stranded miRNA with two-base single-stranded 3′ ends by Dicer in conjunction with the double-stranded RNA-binding protein TRBP (step 3). Finally, one of the two strands is incorporated into an RISC complex, where it is bound by an Argonaute protein (step 4). See P. D. Zamore and B. Haley, 2005, *Science* **309**:1519.

Finally, one of the two strands is selected for assembly into a mature ***R*NA-*i*nduced *s*ilencing *c*omplex (RISC)** containing a single-stranded mature miRNA bound by a multidomain **Argonaute**

protein, a member of a protein family with a recognizable conserved sequence. Several Argonaute proteins are expressed in some organisms, especially plants, and are found in distinct RISC complexes with different functions. Humans express four Argonaute proteins that can each associate with a miRNA to produce a RISC with a miRNA with a seed sequence that can base-pair to a target mRNA, stimulating its deadenyation and degradation (Figure 9-30a). Ago2 is also able to catalyze mRNA cleavage. The four human Argonaute proteins have partially overlapping functions, demonstrated by experiments that show that knock-out of all four human Argonaute proteins is lethal to human embryonic stem cells, but any one of the four is sufficient for viability.

The miRNA-RISC complexes associate with target mRNPs by base pairing between the Argonaute-bound mature miRNA and complementary regions in the 3′ untranslated regions (3′ UTRs) of target mRNAs (see Figure 9-31). Generally, the more RISC complexes are bound to the 3′ UTR of an mRNA, the greater the repression. This allows combinatorial regulation of by separately regulating the transcription of two or more different pri-miRNAs, which are processed to miRNAs required in combination to repress a specific target mRNA.

Approximately 600 different human miRNAs have been observed, most of them expressed only in specific cell types. This has raised the question about the function of miRNAs in differentiation. In one

example, a specific miRNA called *miR-133* is induced when myoblasts differentiate into muscle cells. miR-133 suppresses the translation of PTB, a regulatory splicing factor that functions similarly to Sxl in *Drosophila* (see Figure 9-18). PTB binds to the 3′ splice-site region in the pre-mRNAs of many genes, leading to exon skipping or use of alternative 3′ splice sites. When miR-133 is expressed in differentiating myoblasts, the PTB concentration falls. As a result, alternative isoforms of multiple proteins important for muscle-cell function are expressed in the differentiated cells.

Other examples of miRNA regulation in differentiation in various organisms are being discovered at a rapid pace. Knocking out the *Dicer* gene eliminates the generation of miRNA in mammals. This causes embryonic death early in mouse development. However, when *Dicer* is knocked out only in limb primordia, the influence of miRNA on the development of limbs in the mouse can be observed because limbs are not essential for viability in a laboratory mouse (Figure 9-33). Although all major cell types differentiate and the fundamental aspects of limb patterning are maintained, development is abnormal — demonstrating the importance of miRNAs in regulating the proper level of translation of multiple mRNAs. In effect, miRNAs tune gene expression to the appropriate level for gene function in various cell types. Of the ∼600 human miRNAs, 53 appear to be unique to primates. It seems likely that new miRNAs arose readily during evolution by the duplication of a

pri-miRNA gene followed by mutation of bases encoding the mature miRNA.

EXPERIMENTAL FIGURE 9-33 miRNA function in limb development. Micrographs comparing normal (*left*) and *Dicer* knockout (*right*) limbs of embryonic development day-13 mouse embryos immunostained for the Gd5 protein, a marker of joint formation. *Dicer* is knocked out in developing mouse embryo limb buds by conditional expression of Cre to induce deletion of the *Dicer* gene only in these cells (see Figure 6-40).

[From B. D. Harfe et al., 2005, "The RNaseIII Enzyme Dicer Is Required for Morphogenesis but Not Patterning of the Vertebrate Limb," *Proc. Natl. Acad. Sci. USA* **102**(31):10898–10903.]

Alternative Polyadenylation and mRNA Regulation by miRNAs

The use of alternative polyadenylation sites in mRNA processing, discussed earlier, adds another avenue of regulation of gene expression by miRNAs. For mRNAs expressed from the same gene that use alternative polyadenylation sites, additional miRNA-binding

sites may be located in the mRNA with the longer 3′ exon. As a consequence, mRNAs with the same protein-coding sequence may be regulated differently in alternative cell types depending on the miRNAs expressed in the cells. Consequently, alternative polyadenylation can indirectly regulate mRNAs encoding the same protein as a consequence of miRNA control of translation and mRNA stability.

RNA Interference Induces Degradation of Precisely Complementary mRNAs

RNA interference (RNAi) was discovered unexpectedly during attempts to experimentally manipulate the expression of specific genes. Researchers tried to inhibit the expression of a gene in *C. elegans* by microinjecting a single-stranded, complementary RNA that would hybridize to the encoded mRNA and prevent its translation, a method called *antisense inhibition*. But in control experiments, perfectly base-paired double-stranded RNA a few hundred base pairs long was much more effective at inhibiting expression of the gene than the antisense strand alone (see Figure 6-41). Similar inhibition of gene expression by an introduced double-stranded RNA soon was observed in plants. In each case, the double-stranded RNA induced degradation of all cellular RNAs containing a sequence that was exactly the same as one strand of the double-stranded RNA. Because of the specificity of RNA interference in

targeting mRNAs for destruction, it has become a powerful experimental tool for studying gene function.

Subsequent biochemical studies with extracts of *Drosophila* embryos showed that a long double-stranded RNA that mediates interference is initially processed into a double-stranded short interfering RNA (siRNA). The strands in siRNA contain 21–23 nucleotides hybridized to each other so that the two bases at the 3′ end of each strand are single stranded. Further studies revealed that the cytoplasmic double-stranded RNA-specific ribonuclease that cleaves long double-stranded RNA into siRNAs is the same Dicer enzyme involved in processing pre-miRNAs after their nuclear export to the cytoplasm (see Figure 9-32). This discovery led to the realization that RNA interference and miRNA-mediated translational repression and target mRNA degradation are related processes. In both cases, the mature, short single-stranded RNA, either mature siRNA or mature miRNA, is assembled into a RISC complex in which the short RNAs are bound by an Argonaute protein. When bound to a short RNA that base-pairs extensively with its target RNA, the RISC complex induces target mRNA cleavage. By contrast, a RISC complex associated with a short RNA, which base pairs less extensively (see Figure 9-31a), results in inhibition of translation and a slower form of target mRNA degradation.

In humans, the Argonaute 2 protein is responsible for cleavage of target RNA in an RNAi complex; one domain of the Argonaute

protein is homologous to RNase H enzymes that degrade the RNA of an RNA-DNA hybrid. When the 5′ end of the short RNA of a RISC complex base-pairs precisely with a target mRNA, this domain cleaves the phosphodiester bond of the target RNA across from nucleotides 10 and 11 of the siRNA (see Figure 9-31b). The cleaved RNAs are released and subsequently degraded by cytoplasmic exosomes and the Xrn1 5′ exoribonuclease. If base pairing is less extensive, the Argonaute domain does not cleave or release the target mRNA. Instead, translation is inhibited and the mRNA it is degraded by a different and slower mechanism than the degradation pathway initiated by RISC cleavage of a perfectly complementary target RNA.

When double-stranded RNA is introduced into the cytoplasm of eukaryotic cells, it enters the pathway for assembly of siRNAs into a RISC complex because it is recognized by the cytoplasmic Dicer enzyme and TRBP double-stranded RNA-binding protein that process pre-miRNAs (see Figure 9-32). This process of RNA interference is believed to be an ancient cellular defense against viruses and mobile genetic elements in both plants and animals. Plants with mutations in the genes encoding Dicer and RISC proteins exhibit increased sensitivity to infection by RNA viruses and increased movement of *transposons* within their genomes. The double-stranded RNA intermediates generated during replication of RNA viruses are thought to be recognized by the Dicer ribonuclease, inducing an RNAi response that ultimately degrades viral mRNAs.

During transposition, transposons are inserted into cellular genes in a random orientation, and their transcription from different promoters produces complementary RNAs that can hybridize with each other, initiating the RNAi system that then interferes with the expression of transposon proteins required for additional transpositions.

In plants and *C. elegans* the RNAi response can be induced in all cells of the organism by introduction of double-stranded RNA into just a few cells. Such organism-wide induction requires production of a protein that is homologous to the RNA replicases of RNA viruses. It has been revealed that double-stranded siRNAs are replicated and then transferred to other cells in these organisms. In plants, transfer of siRNAs might occur through plasmodesmata, the cytoplasmic connections between plant cells that traverse the cell walls between them (see Figure 20-38). Organism-wide induction of RNA interference does not occur in *Drosophila* or mammals, presumably because their genomes do not encode RNA-replicase homologs.

In mammalian cells, the introduction of long RNA-RNA duplex molecules into the cytoplasm results in the generalized inhibition of protein synthesis via the PKR pathway, discussed further below. This greatly limits the use of long double-stranded RNAs to experimentally induce an RNAi response against a specific targeted mRNA in mammalian cells as opposed to *Drosophila* cells. Fortunately, researchers discovered that double-stranded siRNAs

21–23 nucleotides in length with two-base 3′-single-stranded regions lead to the generation of single-stranded RNAs that are incorporated into functional siRNA RISC complexes without inducing the generalized inhibition of protein synthesis. This has allowed researchers to use synthetic double-stranded siRNAs to "knock down" the expression of specific genes in human cells as well as in those of other mammals. Also, expression vectors for designed pri-miRNAs can be introduced into cells, leading to the processing of designed siRNAs that hybridize to specific, experimentally controlled target mRNAs, causing their degradation. These methods of **siRNA knockdown** are now widely used in studies of diverse processes, including the RNAi pathway itself!

Cytoplasmic Polyadenylation Promotes Translation of Some mRNAs

In addition to repression by miRNAs, other protein-mediated controls help regulate expression of some genes. Regulatory sequences, or elements, in mRNAs that interact with specific proteins to control translation are generally present in the untranslated region (UTR) at the 3′ or 5′ end of an mRNA. Here we discuss a type of protein-mediated translational control involving 3′ regulatory elements. A different mechanism involving RNA-binding proteins that interact with 5′ regulatory elements is discussed later.

Translation of many eukaryotic mRNAs is regulated by sequence-specific RNA-binding proteins that bind cooperatively to neighboring sites in 3′ UTRs. This allows them to function in a combinatorial manner, similar to the cooperative binding of transcription factors to regulatory sites in an enhancer or promoter region. In most cases studied, translation is repressed by protein binding to 3′ regulatory elements and regulation results from derepression at the appropriate time or place in a cell or developing embryo. The mechanism of such repression is best understood for mRNAs that must undergo *cytoplasmic polyadenylation* before they can be translated.

Cytoplasmic polyadenylation is a critical aspect of gene expression in the early embryo of animals. The egg cells (oocytes) of multicellular animals contain many mRNAs, encoding numerous different proteins that are not translated until after the egg is fertilized by a sperm cell. Some of these "stored" mRNAs have a short poly(A) tail, consisting of only ∼20–40 A residues, to which just a few molecules of cytoplasmic poly(A)-binding protein (PABPCI) can bind. Multiple PABPCI molecules bound to the long poly(A) tail of an mRNA interact with the eIF4G initiation factor, thereby stabilizing the interaction of the mRNA 5′ cap with eIF4E, which is required for translation initiation (see Figure 5-36). Because this stabilization cannot occur with mRNAs that have short poly(A) tails, such mRNAs stored in oocytes are not translated efficiently. At the appropriate time during oocyte maturation or after fertilization of

an egg cell, usually in response to an external signal, approximately 150 A residues are added to the short poly(A) tails on these mRNAs in the cytoplasm, stimulating their translation.

Studies with mRNAs stored in *Xenopus* oocytes have helped elucidate the mechanism of this type of translational control. Experiments in which short-tailed mRNAs are injected into oocytes have shown that two sequences in their 3′ UTR are required for their polyadenylation in the cytoplasm: the AAUAAA poly(A) signal that is also required for the nuclear polyadenylation of pre-mRNAs, and one or more copies of an upstream U-rich *cytoplasmic polyadenylation element (CPE)* (Figure 9-34). This regulatory element is bound by a highly conserved *CPE-binding protein (CPEB)* that contains an RRM domain and a zinc-finger domain.

FIGURE 9-34 Model for control of cytoplasmic polyadenylation and translation initiation. *Left:* In immature oocytes, mRNAs containing the U-rich cytoplasmic polyadenylation element (CPE) have short poly(A) tails and are translationally dormant. CPE-binding protein (CPEB) mediates repression of translation through the interactions depicted, which prevent assembly of an initiation complex at the 5′ end of the mRNA. *Right:* Hormone stimulation of oocytes activates a protein kinase that phosphorylates CPEB, causing it to release Maskin. The cleavage and polyadenylation specificity factor (CPSF) then bind to the poly(A) site, interacting with both bound CPEB and the cytoplasmic form of poly(A) polymerase (PAP).

After the poly(A) tail is lengthened, multiple copies of the cytoplasmic poly(A)-binding protein I (PABPC1) can bind to it and interact with eIF4G, which functions with other initiation factors to bind the 40S ribosome subunit and initiate translation (translationally active). See R. Mendez and J. D. Richter, 2001, *Nat. Rev. Mol. Cell Biol.* **2**:521.

In the absence of a stimulatory signal, CPEB bound to the U-rich CPE interacts with the protein Maskin, which in turn binds to eIF4E associated with the mRNA 5′ cap (Figure 9-34, *left*). As a result, eIF4E cannot interact with other initiation factors and the 40S ribosomal subunit, so translation initiation is blocked. During oocyte maturation, a specific CPEB serine is phosphorylated, causing Maskin to dissociate from the complex. This allows cytoplasmic forms of the cleavage and polyadenylation specificity factor (CPSF) and poly(A) polymerase to bind to the mRNA cooperatively with CPEB. Once the poly(A) polymerase catalyzes the addition of A residues, PABPCI can bind to the lengthened poly(A) tail, leading to the stabilized interaction of all the factors needed to initiate translation (Figure 9-34, *right*; see also Figure 5-36). In the case of *Xenopus* oocyte maturation, the protein kinase that phosphorylates CPEB is activated in response to the hormone progesterone. Thus timing of the translation of stored mRNAs encoding proteins needed for oocyte maturation is regulated by this external signal.

Considerable evidence indicates that a similar mechanism of translational control plays a role in learning and memory. In the central nervous system, the axons from a thousand or so neurons can make connections (synapses) with the dendrites of a single

postsynaptic neuron (see Figure 23-3). When one of these axons is stimulated, the postsynaptic neuron "remembers" which one of these thousands of synapses was stimulated. The next time that synapse is stimulated, the strength of the response triggered in the postsynaptic cell differs from the first time. This change in response has been shown to result largely from the translational activation of mRNAs stored in the region of the synapse in the postsynaptic neuron, leading to the local synthesis of new proteins that increase the size and alter the neurophysiological characteristics of the synapse. The finding that CPEB is present in neuronal dendrites has led to the proposal that cytoplasmic polyadenylation stimulates translation of specific mRNAs in dendrites, much as it does in oocytes. In this case, presumably, synaptic activity (rather than a hormone) is the signal that induces local phosphorylation of CPEB and subsequent activation of translation in one specific synapse of the neuron.

Protein Synthesis Can Be Globally Regulated

Like proteins involved in other processes, translation initiation factors and ribosomal proteins can be regulated by post-translational modifications such as phosphorylation. Such mechanisms affect the translation rate of most mRNAs and hence the overall rate of cellular protein synthesis. The *TOR pathway*,

which represses translation when the supply of amino acids is low as sensed through communication between lysosomes and the cytosol, is discussed in detail in Chapter 21. Other mechanisms that control the global rate of cellular translation include mechanisms that control the activity of translation initiation factor *eIF2*. Here we will focus on the mechanisms that can regulate the initiation of translation.

Global regulation of protein synthesis by regulating translation initiation is mediated by eIF2 kinases. Figure 5-36 summarizes the steps in translation initiation. Translation initiation factor eIF2 brings the charged initiator tRNA to the small ribosome subunit P site. eIF2 is a *trimeric G protein* and exists in either a GTP-bound or a GDP-bound conformation. Only the GTP-bound form of eIF2 is able to bind the charged initiator tRNA and associate with the small ribosomal subunit. The small subunit with bound initiation factors and charged initiator tRNA then interacts with the eIF4 complex bound to the 5′ cap of an mRNA via its eIF4E subunit. The small ribosomal subunit then scans down the mRNA in the 3′ direction until it reaches an AUG initiation codon that can base-pair with the initiator tRNA in its P site. When this occurs, the GTP bound by eIF2 is hydrolyzed to GDP and the resulting eIF2·GDP complex is released. GTP hydrolysis results in an irreversible “proofreading” step that prepares the small ribosomal subunit to associate with the large subunit only when an initiator tRNA is properly bound in the P site and is properly base-paired with the AUG start codon. Before

eIF2 can participate in another round of initiation, its bound GDP must be replaced with a GTP. This process is catalyzed by the translation initiation factor eIF2B, a guanine nucleotide exchange factor (GEF) specific for eIF2.

A mechanism for inhibiting general protein synthesis in stressed cells involves phosphorylation of the eIF2α subunit at a specific serine. Phosphorylation at this site does not interfere with eIF2 function in protein synthesis directly. Rather, phosphorylated eIF2 has very high affinity for the eIF2 guanine nucleotide exchange factor, *eIF2B*, which cannot release the phosphorylated eIF2 and consequently is blocked from catalyzing GTP exchange by additional eIF2 factors. Since there is an excess of eIF2 over eIF2B, phosphorylation of a fraction of eIF2 results in inhibition of all the cellular eIF2B. The remaining eIF2 accumulates in its GDP-bound form, which cannot participate in protein synthesis, thereby inhibiting nearly all protein synthesis in the cell.

However, some mRNAs have 5′ regions that allow translation initiation at the low eIF2-GTP concentration that results from eIF2 phosphorylation. These mRNAs include those for chaperone proteins that function to refold cellular proteins denatured as the result of cellular stress, additional proteins that help the cell to cope with stress, and transcription factors that activate transcription of the genes encoding these stress-induced proteins.

Human cells contain four eIF2 kinases that phosphorylate the same inhibitory eIF2 α serine. Each of these is regulated by a different type of cellular stress, inhibiting protein synthesis and allowing cells to divert the large fraction of cellular resources usually devoted to protein synthesis in growing cells for use in responding to the stress:

- The *GCN2* (general control non-derepressible 2) eIF2-kinase is activated by binding uncharged tRNAs. The concentration of uncharged tRNAs increases when cells are starved for amino acids, activating GCN2 eIF2-kinase activity and greatly inhibiting protein synthesis.
- *PEK* (pancreatic eIF2 kinase) is activated when proteins translocated into the endoplasmic reticulum (ER) do not fold properly because of abnormalities in the ER lumen environment. Inducers include abnormal carbohydrate concentrations, because this inhibits the glycosylation of many ER proteins. Inactivating mutations in an ER chaperone required for proper folding of many ER proteins (Chapters 13 and 14) also results in PEK activation.
- *Heme-regulated inhibitor (HRI)* is another eIF2 kinase activated in developing red blood cells when the supply of the heme prosthetic group is too low to accommodate the rate of globin protein synthesis. This negative feedback loop lowers the rate of globin protein synthesis until it matches the rate of heme synthesis. HRI is also activated in other types of cells in response to oxidative stress or heat shock.

- *Protein kinase RNA activated (PKR)* is activated by double-stranded RNAs longer than ∼30 base pairs. Under normal circumstances in mammalian cells, such double-stranded RNAs are produced only during a viral infection. Long regions of double-stranded RNA are generated in replication intermediates of RNA viruses or from hybridization of complementary regions of RNA transcribed from both strands of DNA virus genomes. Inhibition of protein synthesis prevents the production of progeny virions, protecting neighboring cells from infection. Interestingly, adenoviruses evolved a defense against PKR: they express prodigious amounts of an ∼160-nucleotide virus-associated (VA) RNA with long double-stranded hairpin regions. VA RNA is transcribed by RNA polymerase III and exported from the nucleus by Exportin5, the exportin for pre-miRNAs (see Figure 9-32). VA RNA binds to PKR with high affinity, inhibiting its protein kinase activity and preventing the inhibition of protein synthesis observed in cells infected with a mutant adenovirus from which the VA gene was deleted.

Sequence-Specific RNA-Binding Proteins Control Specific mRNA Translation

In contrast to global mRNA regulation, mechanisms have also evolved for controlling the translation of certain specific mRNAs. This is usually done by sequence-specific RNA-binding proteins that

bind to a particular sequence or RNA structure in the mRNA. When binding is in the 5′ untranslated region (5′ UTR) of an mRNA, the 40S ribosomal subunit's ability to scan to the first initiation codon is blocked, inhibiting translation initiation. Binding in other regions can either promote or inhibit mRNA degradation.

Control of intracellular iron concentration is an elegant example of the protein-mediated regulation of the translation of one mRNA and the degradation of another. This is accomplished by ***Iron Response Element Binding Proteins* (IRE-BPs)**, including the bifunctional protein aconitase 1 (encoded by the ACO1 gene, alias *IRE-BP1*) and its paralog *IRE-BP2* (encoded by the IREB2 gene). Precise regulation of cellular iron ion concentration is critical to the cell. Multiple enzymes and proteins contain Fe^{2+} as a cofactor, such as enzymes of the TCA cycle (see Figure 12-16) and electron-carrying proteins involved in the generation of ATP by mitochondria and chloroplasts (Chapter 12). On the other hand, excess Fe^{2+} generates free radicals that react with and damage cellular macromolecules. When intracellular iron stores are low, a dual-control system operates to increase the level of cellular iron; when iron is in excess, the system operates to store the iron in an inert form that prevents accumulation of toxic levels of free Fe^{2+} ions.

IRE-BPs are 4Fe-4S cluster-containing proteins that act as cellular iron sensors. When the cytosolic Fe^{2+} concentration is too low, the iron in the Fe-S clusters dissociates from the protein and the IRE-BP

becomes an active RNA-binding protein that binds to a specific nucleotide sequence within stem-loop secondary structures in the untranslated regions of the ferritin and transferrin receptor mRNAs. These *I*ron *R*esponse *E*lements (IREs) in these mRNAs are located in the 5′ untranslated region of the ferritin mRNAs (Figure 9-35a) and in the 3′ untranslated sequence in the transferrin receptor (TfR) mRNA. Ferritin is composed of 24 subunits of a ferritin heavy chain and an equal number of ferritin light chains. They form a large intracellular protein complex that binds and stores excess cellular iron. When an IRE-BP is in its RNA-binding conformation at low cellular Fe^{2+} concentration, it recognizes and binds five specific bases in the IRE loop and the duplex nature of the stem in the mRNA for both heavy and light ferritin chains (Figure 9-35a). The bound IRE-BP blocks the small ribosomal subunit from scanning for the AUG start codon (see Figure 5-36), thereby inhibiting translation initiation. This causes a decrease in ferritin protein production and results in less iron being stored within the ferritin complex, making more iron available to iron-requiring enzymes. At high iron concentrations, the IRE-BP is in a conformation where it cannot bind the IREs in the 5′ untranslated region of the ferritin mRNAs. Consequently, ferritin translation is not inhibited, and newly synthesized ferritin can store free Fe^{2+}, thus prevent its accumulation to harmful levels within the cell.

FIGURE 9-35 Iron-dependent regulation of mRNA translation and degradation. The iron response element–binding protein (IRE-BP) controls (a) translation of ferritin mRNA and (b) degradation of transferrin-receptor (TfR) mRNA. At low intracellular iron concentrations IRE-BP binds to iron-response elements (IREs) in the 5′ or 3′ untranslated region of these mRNAs. At high iron concentrations, IRE-BP undergoes a conformational change and cannot bind either mRNA. The dual control by IRE-BP precisely regulates the level of free iron ions within cells. See the text for discussion.

The second mRNA regulated by IRE-BPs is regulated differently: it encodes the transferrin receptor (TfR). In vertebrates, iron is carried through the circulatory system bound to a protein called *transferrin*. After binding to the transferrin receptor (TfR) in the plasma membrane of most cell types, the transferrin-iron complex is brought into cells by receptor-mediated endocytosis (see Chapter 14; Figure 14-31). The 3′-untranslated region of TfR mRNA contains multiple IREs with AU-rich element destabilizing sequences interspersed between the stem-loop structures (see above). At high Fe^{2+} concentrations, when the IRE-BP is unable to bind to the IRE, these AU-rich elements promote degradation of TfR mRNA by the same mechanism that leads to rapid degradation of other short-lived mRNAs with AU-rich elements, as described previously. The

resulting decrease in production of the transferrin receptor quickly reduces iron import, thus protecting the cell from excess iron. At low Fe^{2+}, concentrations, however, the IRE-BP binds to the 3′ IREs in TfR mRNA and blocks access of proteins to the destabilizing AU-rich elements. As a result, TfR mRNA levels increase, leading to increased production of the transferrin receptor protein and more iron transport into the cell. As a consequence of these two mechanisms of post-translational control, regulation of translation of the ferritin mRNAs and regulation of stability of the transferrin mRNA, the intracellular Fe^{2+} concentration is held at the concentration required for binding of Fe^{2+} to iron-requiring enzymes and is prevented from reaching higher concentrations that would be toxic.

Other regulated RNA-binding proteins may also function to control mRNA translation or degradation. For example, a heme-sensitive RNA-binding protein controls translation of the mRNA encoding aminolevulinate (ALA) synthase, a key enzyme in the synthesis of heme. Similarly, in vitro studies have shown that the mRNA encoding the milk protein casein is stabilized by the hormone prolactin and rapidly degraded in its absence.

Surveillance Mechanisms Prevent Translation of Improperly Processed mRNAs

Translation of an improperly processed mRNA could lead to production of a nonfunctional or abnormally functioning protein. This effect is equivalent to that resulting from dominant-negative mutations, discussed in Chapter 6 (see Figure 6-2). Several mechanisms collectively termed **mRNA surveillance** help cells avoid the translation of improperly processed mRNA molecules. We have previously mentioned two such surveillance mechanisms: the recognition of improperly processed pre-mRNAs in the nucleus and their degradation by the nuclear exosome, and the general restriction against nuclear export of incompletely spliced pre-mRNAs that remain associated with a spliceosome assembly intermediate.

Nonsense-Mediated Decay (NMD)

This mechanism of mRNA surveillance causes degradation of mRNAs in which one or more exons have been incorrectly spliced. Such incorrect splicing will often alter the open reading frame of the mRNA 3′ to the improper exon junction, resulting in introduction of an out-of-frame missense mutation and an incorrect stop codon. For nearly all properly spliced mRNAs, the stop codon is in the last exon. The process of nonsense-mediated decay results in the rapid degradation of mRNAs with stop codons that occur before the last splice junction in the mRNA, since in most cases such mRNAs arise from errors in RNA splicing. However, NMD can also result from a mutation creating a stop codon within a gene or a frame-shifting

deletion or insertion. NMD was initially discovered during the study of patients with β^0-thalasemia, who produce a low level of β-globin protein associated with a low level of β-globin mRNA (Figure 9-36).

FIGURE 9-36 Discovery of nonsense-mediated mRNA decay (NMD). (a) Patients with β^0-thalassemia express very low levels of β-globin mRNA. A common cause of this syndrome is a single-base-pair deletion in exon 1 or exon 2 of the β-globin gene. Ribosomes translating the mutant mRNA read out of frame following the deletion and encounter a stop codon in the wrong reading frame before they translate across the last exon junction in the mRNA. Consequently, they do not displace an exon-junction complex (EJC) from the mRNA. Cytoplasmic proteins associate with the EJC and induce degradation of the mRNA. (b) Bone marrow was obtained from a patient with a wild-type β-globin gene and from a patient with β^0-thalassemia. RNA was isolated from the bone marrow cells shortly after collection, or 30 minutes after incubation in media with Actinomycin D, a drug that inhibits transcription. The

amount of β^0-globin RNA was measured using the S1-nuclease protection method (arrow). The patient with β^0-thalassemia had much less β-globin mRNA than the patient with a wild-type β-globin gene (−Act D). The mutant β-globin mRNA decayed rapidly when transcription was inhibited (+Act D), whereas the wild-type β-globin mRNA remained stable.

[Republished with permission from Elsevier, from L. E. Maquat et al., 1981, "Unstable β-Globin mRNA in mRNA-Deficient β^0 Thalassemia," *Cell* **27**(3):543–553; permission conveyed through Copyright Clearance Center, Inc.]

A search for possible molecular signals that might indicate the positions of splice junctions in a processed mRNA led to the discovery of exon-junction complexes. As noted already, these complexes of several proteins (including a core complex of eIF4AIII, MLN51, MAGOH, and Y14 proteins and peripheral factors including REF), bind ∼20 nucleotides 5′ to an exon-exon junction following RNA splicing, and stimulate export of mRNPs from the nucleus by interacting with the mRNA exporter, NXT1/NXF1 (see Figure 9-26). Analysis of yeast mutants indicated that one of the peripheral proteins associated with exon-junction complexes in the nucleus, UPF3, functions in nonsense-mediated decay (see Figure 9-37, step **1**). UPF3 remains associated with the EJC as it is exported through a nuclear pore complex, and associates with the cytoplasmic NMD factor UPF2 (see Figure 9-37, step **2**). During translation termination, eukaryotic release factors 1 and 3 (eRF1 and eRF3) associate with ribosomes with a stop codon in the A site (see Figure 5-38). NMD factors UPF1 and SMG1, a protein kinase, associate with eRF1 and eRF3 forming a complex called the *SURF* complex (step **3**) associated with the terminating ribosome. The SURF complex

associates, via an interaction between UPF1 and UPF2, with any UPF2 that remains associated with EJC complexes on the mRNA that were not displaced from the mRNA by a translating ribosome (step **4**). This leads to the phosphorylation of UPF1 by SMG1, which promotes the release of eRF1 and eRF3 and the binding of NMG factor SMG7. Finally, SMG7 causes the mRNP to associate with P bodies, inhibiting translation. UPF2 then binds a P body–associated deadenylase complex that rapidly removes the poly(A) tail from an associated mRNA, leading to its decapping and degradation by the P body–associated $5' \rightarrow 3'$ exonuclease Xrn1 (see Figure 9-30a).

FIGURE 9-37 (a) Nonsence Mediated Decay (NMD). Step **1**: An abnormal mRNA with a premature termination codon (PTC) is produced in the nucleus as the result of abnormal RNA splicing. An exon junction complex (EJC) is left at a splice junction following RNA-splicing and associates with NMD factor UPF3. Step **2**: After export to the cytoplasm, NMD factor UPF2 associates with UPF3 bound to the EJC. A ribosome also initiates translation

and reaches the PTC. Step 3: Eukaryotic release factors 1 (eRF1) and 3 (eRF3) (see Figure 5-38) associate with the ribosome stopped at the termination codon and associate with UPF1 and protein kinase SMG1, forming a "SURF complex" associated with the terminating ribosome. Step 4: Any EJCs associated with mRNA that were not displaced by a translating ribosome, interact with the terminating ribosome through an interaction between UPF2 associated with the EJC and UPF1 associated with the SURF complex, leading to SMG1 phorphorylation of UPF1. Step 5: NMD factor SMG7 binds phosphorylated UPF1 as eRF1 and eRF3 are released. Step 6: Bound SMG7 causes the mRNP complex to associate with P-bodies where translation is inhibited and the abnormal mRNA is degraded. (b) Non-stop decay. (c) No-go decay. Bottom, diagram of ribosomes "stacking up" 5′ to a stalled ribosome. See NL Garneau, J Wilusz, and CJ Wilusz Nature Reviews *Mol Cell Biol* **8**:113 (2007); Part (c) Simms CL et al. (2017) *Mol. Cell* **68**, 361–373.

In the case of a properly spliced mRNA, the current hypothesis is that during translation of the mRNA by the first "pioneer" ribosome to translate the mRNA, EJCs are displaced from the mRNP. However, for mRNAs with a stop codon before the final exon junction, one or more EJCs remain associated with the mRNA, resulting in nonsense-mediated decay (Figure 9-37a).

Non-Stop Decay

This alternative mechanism of mRNA surveillance leads to the inhibition of translation and degradation of mRNAs that have been prematurely polyadenylated so that a translating ribosome does not encounter an in-frame stop codon and translation continues to the end of the poly(A) where the ribosome arrests, still tightly bound to the mRNA (Figure 9-37b). Such ribosomes associated with the 3′ end of an mRNA without terminating translation by the normal

mechanism involving peptide release factors (Figure 5-38) are recognized by the protein Ski7. The C-terminus of Ski7 is similar in structure to the GTPase domains of elongation factor-1A (EF1A) (see Figure 5-37) and peptide release factor eRF3 (see Figure 5-38) that bind to the empty A site of the ribosome. Ski7 is proposed to bind to the A site similarly, causing release of the ribosome from the mRNA. Ski7 then recruits the exosome to deadenylate and then rapidly decay the transcript in the $3' \rightarrow 5'$ direction.

No-Go Decay

This is the final mechanism of mRNA quality control in the cytoplasm we will discuss in this chapter. This releases ribosomes that are stalled during translation due to damage to the mRNA template or the presence of an unusually large and stable secondary structure in the mRNA $5'$ of the stop codon (see Figure 9-37c). A recent study indicates that ribosome collision is a critical trigger for mRNA cleavages that occur in the initial step of no-go decay. Ribosome collision occurs when ribosomes stack-up along the mRNA $5'$ to the block to ribosome translocation (see Figure 9-37c, *bottom*). This was detected experimentally because mRNAs with engineered long, stable stem loops that block ribosome translocation ("no-go mRNAs") exhibit regions of protection in 30 base intervals $5'$ to the block when RNase is added to mildly cross-linked, permeabilized cells treated as in the procedure for chromatin immunoprecipitation (Figure 8-12a, Step **1**). This

protection of the no-go mRNA in 30-base intervals presumably results from protection of the mRNA in the channel of the 30S ribosomal subunits (Figure 5-34) stacked up along the mRNA.

In vivo, this stacking up of ribosomes 5′ to the block to ribosome translocation causes endonucleolytic cleavage of the no-go mRNA. Although the endonuclease that does this has not been identified, it seems likely to be associated with the ribosome since deep sequencing revealed that cleavage sites in no-go mRNAs occur in regions of the mRNA within the mRNA channels of 30S subunits (see Figure 5-34) phased behind the block to translocation. In humans, the E3 ubiquitin ligase ZNF598 polyubiquitinylates several ribosomal proteins leading to their proteosomal degradation as well as degradation of nascent polypeptide and release of the ribosomal subunits from the cleaved ends of the no-go mRNA. This is followed by degradation of the 5′ fragment of the cleaved no-go mRNA by cytoplasmic exosomes and degradation of the 3′ fragment by cytoplasmic XRN1 (Figure 9-37c).

Localization of mRNAs Permits Production of Proteins at Specific Regions Within the Cytoplasm

Many cellular processes depend on localization of particular proteins to specific structures or regions of the cell. In later

chapters, we examine how some proteins are transported *after* their synthesis to their proper cellular location. Alternatively, protein localization can be achieved by localization of mRNAs to specific regions of the cytoplasm in which their encoded proteins function. In most cases examined thus far, such mRNA localization is specified by sequences in the 3′ untranslated region of the mRNA. A recent genomic-level study of mRNA localization in *Drosophila* embryos revealed that ∼70 percent of 3000 mRNAs analyzed were localized to specific subcellular regions, raising the possibility that this is a much more general phenomenon in all metazoa than previously appreciated.

Localization of mRNAs to the Bud in *S. Cerevisiae*

The most thoroughly understood example of mRNA localization occurs in the budding yeast *S. cerevisiae*. As discussed in Chapter 8, whether a haploid yeast cell exhibits the **a** or α mating type is determined by whether **a** or α genes are present at the expressed *MAT* locus on chromosome III (see Figure 8-31). The process that transfers **a** or α genes from a silent mating-type locus near the telomeres of chromosome III to the expressed *MAT* locus is initiated by a sequence-specific endonuclease called *HO*. Transcription of the *HO* gene is dependent on the SWI/SNF chromatin-remodeling complex (see Section 8.4). Daughter yeast cells that arise by budding from mother cells contain a transcriptional repressor called *Ash1* (for *A*symmetric *s*ynthesis of *H*O) that prevents recruitment of the

SWI/SNF complex to the *HO* gene, thereby preventing its transcription. The absence of Ash1 from mother cells allows them to transcribe the *HO* gene. As a consequence, mother cells switch their mating type, while daughter cells generated by budding do not (Figure 9-38).

FIGURE 9-38 Mating-type switching in haploid budding yeast cells. Following nuclear DNA synthesis in *S. cerevisiae*, a haploid yeast cell undergoes mitosis and generates a small daughter cell from a daughter cell bud (Figure 1-24) and a larger mother cell [Cell division 1]. The resulting daughter and mother cells have the same mating type as the parent cell (α in this example, represented by purple color). Before the next cell division, the smaller daughter cell grows in size to the size of a mother cell and then divides [Cell division 2] into a smaller daughter cell and a larger mother cell that have the same mating type as the parental cell (α in this example). In contrast, the larger mother cell generated in Cell division 1 switches its mating type before DNA synthesis and divides into a mother and daughter cell with the

opposite mating type (**a** in this example, represented by orange). This process continues in further divisions so that daughter cells have progeny of the same mating type, while the mother cells have progeny that have switched their mating type compared to their mother.

Ash1 protein accumulates only in daughter cells because the mRNA encoding it is localized to daughter cells. The localization process requires three proteins: She2 (for *S*WI-dependent *HO e*xpression), an RNA-binding protein that binds specifically to a localization signal with a specific RNA structure in the ASH1 mRNA; Myo4, a myosin motor protein that moves cargos on actin filaments (see Chapter 17); and She3, which links She2 and therefore ASH1 mRNA to Myo4 (Figure 9-39). ASH1 mRNA is transcribed in the nucleus of the mother cell before mitosis. Movement of Myo4 with its bound ASH1 mRNA along actin filaments that extend from the mother cell into the bud carries the ASH1 mRNA into the growing bud before cell division.

FIGURE 9-39 Model for restriction of mating-type switching to mother cells in *S. cerevisiae*. Ash1 protein prevents a cell from transcribing the *HO* gene whose encoded protein initiates the DNA rearrangement that results in mating-type switching from α to **a** or **a** to α. Switching occurs only in the mother cell, after it separates from a newly budded daughter cell, because the Ash1 protein is present only in the daughter cell. The molecular basis for this differential localization of Ash1 is the one-way transport of ASH1 mRNA into the bud. A linking protein, She2, binds to specific 3′ untranslated sequences in the ASH1 mRNA and also binds to She3 protein. This protein in turn binds to a myosin motor, Myo4, which moves along actin filaments into the bud. See S. Koon and B. J. Schnapp, 2001, *Curr. Biol.* **11**:R166.

At least 23 other mRNAs were found to be transported by the She2, She3, Myo4 system. All have an RNA localization signal to which She2 binds, usually in their 3′ UTR. The process can be visualized in live cells by the experiment shown in Figure 9-40. RNAs can be fluorescently labeled by including in their sequence high-affinity binding sites for RNA-binding proteins, such as bacteriophage

proteins MS2 coat protein and bacteriophage λN protein, that bind to different stem loops of specific sequence (Figure 9-40a). When such engineered mRNAs are expressed in budding yeast cells along with the bacteriophage proteins fused to proteins that fluoresce different colors, the fusion proteins bind to these specific RNA sequences, thereby labeling the RNAs that contain them with different colors. In the experiment shown in Figure 9-40b, ASH1 mRNA was labeled by the binding of green fluorescent protein fused to λN. Another mRNA localized to the bud by this system, the IST2 mRNA, encoding a component of the growing bud membrane, was labeled by the binding of red fluorescent protein fused to MS2 coat protein. Video of a budding cell showed that the differently labeled ASH1 and IST2 mRNAs accumulated in the same large cytoplasmic RNP particle containing multiple mRNAs in the mother cell cytoplasm, as can be seen from the merge of the green and red fluorescent signals. The RNP particle was then transported into the bud within about one minute.

EXPERIMENTAL FIGURE 9-40 Transport of mRNP particles from a yeast mother cell into the bud. (a) Yeast cells were engineered to express an Ash1 mRNA with binding sites for the bacteriophage λN protein in its 5′ untranslated region and an IST2 mRNA with binding sites for bacteriophage MS2 coat protein in its 3′ untranslated region. A fusion of green fluorescent protein to λN protein (GFP-λN) and a fusion of red fluorescent protein to MS2 coat protein (RFP-MS2) also were expressed in the same cells. In other experiments, these fluorescently tagged sequence-specific RNA-binding proteins were shown to bind to their own specific binding sites engineered

into the ASH1 and IST2 mRNAs, and not to each others' binding sites. Both fluorescently tagged proteins also contained a nuclear localization signal so that the fluorescent proteins that were not bound to their high-affinity binding sites in these mRNAs were transported into nuclei through nuclear pore complexes (see Chapter 13). This was necessary to prevent high fluorescence from excess GFP-λN and RFP-MS2 in the cytoplasm. At the right, GFP-λN and RFP-MS2 were independently visualized by using millisecond alternating laser excitation of GFP and RFP. (b) Frames from a video of fluorescing cells are shown. The nucleus next to the large vacuole in the mother cell near the center of the micrographs, as well as nuclei in neighboring cells, was observed by green and red fluorescence as shown in the top and middle rows. A merge of the two images is shown in the bottom row, which also indicates the time elapsed between images. An RNP particle containing both the ASH1 mRNA with λN-binding sites and the IST2 mRNA with MS2-binding sites was observed in the mother cell cytoplasm in the left column of images (arrow). The particle increased in intensity between 0.00 and 46.80 seconds, indicating that more of these mRNAs joined the RNP particle. The RNP particle was transported into the bud between 46.80 and 85.17 seconds and then became localized to the bud tip.

As discussed above in the section on P bodies, cytoplasmic sites of mRNA decay, formation of the large cytoplasmic granules of RNPs observed here (Figure 9-40b) and in other examples of transported RNA granules in cells of multicellular eukaryotes requires sequences in the RNA-binding protein composed of a low complexity amino acid sequence such as repeats of [G/S]Y[G/S]. Peptides containing these low complexity sequences spontaneously associate in vitro by a process referred to as "liquid-liquid phase separation" discussed in Chapter 8 in regard to formation of

transcriptional condensates in the nucleus (Figure 8-38). The condensates formed in vitro from these peptides with simple sequence repeats can be dissociated by phosphorylation of serines within them. Such liquid-liquid phase separated droplets are probably involved in the formation of the large RNP complexes transported on actin cables in yeast and on microtubules (see Chapters 17 and 18) in large asymmetric cells in higher eukaryotes, such as in the axons and dendrites of nerve cells (see Chapter 23) described in the next section. Regulated phosphorylation of these low complexity sequences in RNA-binding proteins associated with RNP granules may well account for the regulated formation and dissociation of RNP granules such as those observed in Figure 9-40b.

Localization of mRNAs to Synapses in the Mammalian Nervous System

As mentioned earlier, in neurons, localization of specific mRNAs at synapses far from the nucleus in the cell body plays an essential function in learning and memory (Figure 9-41). Like the localized mRNAs in yeast, these mRNAs contain RNA localization signals in their 3′ untranslated region. Some of these mRNAs are initially synthesized with short poly(A) tails that do not allow translation initiation. Once again, large RNP particles containing multiple mRNAs bearing localization signals form in the cytoplasm near the cell nucleus. In this case, the RNP particles are transported down the axon to synapses by kinesin motor proteins that travel down

microtubules extending the length of the axon (see Chapter 18). Membrane depolarization at a given synapse by the regulated opening of ion channels in the plasma membrane (see Chapter 23) may then stimulate the mRNAs' polyadenylation in the region of the synapse, activating the translation of encoded proteins that increase the size and alter the neurophysiological properties of the one synapse while leaving unaffected the hundreds to thousands of other synapses made by the same neuron.

EXPERIMENTAL FIGURE 9-41 A specific neuronal mRNA localizes to synapses. Sensory neurons from the sea slug *Aplysia californica* were cultured with target motor neurons so that axons from the sensory neurons formed synapses with dendrites from the motor neurons in culture. The micrograph at the left shows motor neuron axons visualized with a blue fluorescent dye. GFP-VAMP (green) was expressed in sensory neurons and marks the location of synapses formed between sensory neuron axons and motor neuron dendrites (arrows). The micrograph on the right shows red fluorescence from in situ hybridization of an anti-sensorin mRNA probe. Sensorin is a neurotransmitter expressed only by the sensory neuron; sensory neuron axons are not otherwise visualized in this preparation, but they lie adjacent to the motor neuron dendrites. The in situ hybridization results indicate that sensorin mRNA in the sensory neuron is localized to synapses.

KEY CONCEPTS OF SECTION 9.4

Cytoplasmic Mechanisms of Post-Transcriptional Control

- Most mRNAs are degraded in the cytoplasm as the result of the gradual shortening of the poly(A) tail (deadenylation) followed by exosome-mediated $3' \rightarrow 5'$ digestion, or removal of the $5'$ cap and digestion by a $5' \rightarrow 3'$ exoribonuclease, XRN1 (see Figure 9-30).
- Eukaryotic mRNAs encoding proteins that are expressed in short bursts generally have repeated copies of an AU-rich sequence (AU-rich element) in their $3'$ UTR. Specific proteins that bind to these elements also interact with a deadenylating enzyme complex and cytoplasmic exosomes, promoting rapid mRNA degradation.
- Translation can be repressed by microRNAs (miRNAs), which form imperfect hybrids with sequences in the $3'$ untranslated region (UTR) of specific target mRNAs. mRNAs bound by several miRNAs are concentrated in P bodies in the cytoplasm, where they are degraded by decapping followed by digestion by the cytoplasmic exosome.
- The related phenomenon of RNA interference (RNAi), which probably evolved as an early defense system against viruses and transposons, leads to rapid degradation of mRNAs that form perfect hybrids with short interfering RNAs (siRNAs).
- Both miRNAs and siRNAs are 21–23 nucleotides in length, are generated from longer precursor molecules and are bound by an Argonaute protein and assembled into a multiprotein RNA-induced silencing complex (RISC). RISC complexes either repress translation of target mRNAs and induce their localization to P bodies, where they are degraded (miRNAs), or cleave them (siRNAs), generating unprotected ends that are rapidly degraded by cytoplasmic exosomes and the $5' \rightarrow 3'$ exonuclease XRN1 (see Figures 9-31 and 9-32).
- Cytoplasmic polyadenylation is required for the translation of mRNAs with a short poly(A) tail. This step is regulated in cells: binding of a specific protein to regulatory elements in the $3'$ UTRs represses translation of these mRNAs, and phosphorylation of this RNA-binding protein leads to lengthening of the $3'$ poly(A) tail and thus translation (see Figure 9-34).

- The global rate of cellular protein synthesis is regulated in part by controlling the activity of eukaryotic initiation factor 2 (eIF2) required at an early step in selecting mRNAs for translation (see Figure 5-24). eIF2 kinases respond to various types of cellular stress by phosphorylating a regulatory site in eIF2, inhibiting eIF2 exchange of GTP for GDP and consequently inhibiting an early step in protein synthesis.
- In addition to regulation of the global rate of protein synthesis by most mRNAs, the translation, stability, and cytoplasmic localization of specific mRNAs can be controlled. This is generally accomplished by sequence-specific RNA-binding proteins that bind to regulatory elements in the $3'$ or less commonly the $5'$ UTRs of some mRNAs. For example, translation of ferritin mRNA and degradation of transferrin receptor (TfR) mRNA are both regulated by the same iron-sensitive RNA-binding proteins, IREBP1 and 2. At low iron concentrations, these proteins have an active conformation that binds to specific sequences that form stem-loops in the mRNAs, inhibiting ferritin mRNA translation and degradation of TfR mRNA (see Figure 9-35). This dual control precisely regulates the intracellular Fe^{2+} concentration.
- Nonsense-mediated decay and other mRNA surveillance mechanisms prevent the translation of improperly processed mRNAs encoding abnormal proteins that might interfere with the functioning of the corresponding normal proteins.
- Many mRNAs are transported to specific subcellular locations by sequence-specific RNA-binding proteins that bind localization sequences usually found in the $3'$ UTR. These RNA-binding proteins then associate, directly or via intermediary proteins, with motor proteins that carry large RNP particles, containing many mRNAs bearing the localization signals, on actin or microtubule fibers to specific locations in the cytoplasm.

9.5 Processing of rRNA and tRNA

Approximately 80 percent of the total RNA in rapidly growing mammalian cells (e.g., cultured HeLa cells) is rRNA, and 15 percent is tRNA; protein-coding mRNA thus constitutes only a small portion of the total RNA. The primary transcripts produced from most rRNA genes and from tRNA genes, like pre-mRNAs, are extensively processed to yield the mature, functional forms of these RNAs.

The ribosome is a highly evolved, complex structure (see Figure 5-34), optimized for its function in protein synthesis. Ribosome synthesis requires the function and coordination of all three nuclear RNA polymerases, RNA pol I, II, and III. The 28S and 5.8S rRNAs associated with the large ribosomal subunit and the single 18S rRNA of the small subunit are transcribed by RNA polymerase I. The 5S rRNA of the large subunit is transcribed by RNA polymerase III, and the mRNAs encoding the ribosomal proteins are transcribed by RNA polymerase II. In addition to the four rRNAs and ∼70 ribosomal proteins, at least 150 other RNAs and proteins interact transiently with the two ribosomal subunits during their assembly through a series of coordinated steps. Furthermore, multiple specific bases and riboses of the mature rRNAs are modified to optimize their function in protein synthesis. Although most of the steps in ribosomal subunit synthesis and assembly occur in the nucleolus, some occur in the nucleoplasm during passage from the nucleolus to nuclear pore complexes. A quality-control step occurs before

nuclear export so that only fully functional subunits are exported to the cytoplasm, where the final steps of ribosome subunit maturation occur. tRNAs also are processed from precursor primary transcripts in the nucleus and modified extensively before they are exported to the cytoplasm and used in protein synthesis. First, we'll discuss the processing and modification of rRNA and the assembly and nuclear export of ribosomes. Then we'll consider the processing and modification of tRNAs.

Pre-rRNA Genes Are Similar in All Eukaryotes and Function as Nucleolar Organizers

The 28S and 5.8S rRNAs associated with the large (60S) ribosomal subunit and the 18S rRNA associated with the small (40S) ribosomal subunit in multicellular eukaryotes (and the functionally equivalent rRNAs in all other eukaryotes) are encoded by a single type of pre-rRNA transcription unit. In human cells, transcription by RNA polymerase I yields a 45S ($\sim$13.7 kb) primary transcript (pre-rRNA), which is processed into the mature 28S, 18S, and 5.8S rRNAs found in cytoplasmic ribosomes. The fourth rRNA, 5S, is encoded separately and transcribed outside the nucleolus by RNA polymerase III. Sequencing of the DNA encoding the 45S pre-rRNA from many species showed that this DNA shares several properties in all eukaryotes. First, the pre-rRNA genes are arranged in long

tandem arrays separated by nontranscribed spacer regions ranging in length from $\sim$2 kb in frogs to $\sim$30 kb in humans (Figure 9-42). Second, the genomic regions corresponding to the three mature rRNAs are always arranged in the same $5' \rightarrow 3'$ order: 18S, 5.8S, and 28S. Third, in all eukaryotic cells (and even in bacteria), the pre-rRNA gene codes for regions that are removed during processing and rapidly degraded. These regions probably contribute to proper folding of the rRNAs but are not required once the folding has occurred. The general structure of pre-rRNA genes in several organisms is diagrammed in Figure 9-43.

EXPERIMENTAL FIGURE 9-42 Electron micrograph of pre-rRNA transcription units from the nucleolus of a frog oocyte. Each "feather" represents multiple pre-rRNA molecules associated with protein in a pre-ribonucleoprotein complex (pre-rRNP) emerging from a transcription unit. Note the dense "knob" at the $5'$ end of each nascent pre-RNP thought to be a processome. Pre-rRNA transcription units are arranged in tandem, separated by nontranscribed spacer regions of nucleolar chromatin.

FIGURE 9-43 General structure of eukaryotic pre-rRNA transcription units. The three coding regions (red) encode the 18S, 5.8S, and 28S rRNAs found in ribosomes of multicellular eukaryotes or their equivalents in other species. The order of these coding regions in the genome is always $5' \rightarrow 3'$. Variations in the lengths of the transcribed spacer regions (blue) account for the major difference in the lengths of pre-rRNA transcription units in different organisms.

The synthesis and most of the processing of pre-rRNA occurs in the nucleolus. When pre-rRNA genes initially were identified in the nucleolus by in situ hybridization, it was not known whether any other DNA was required to form the nucleolus. Subsequent experiments with transgenic *Drosophila* strains demonstrated that a single complete pre-rRNA transcription unit induces formation of a small nucleolus. Thus a single pre-rRNA gene is sufficient to be a "nucleolar organizer," and all the other components of the ribosome diffuse to the newly formed pre-rRNA. The structure of the nucleolus observed by light and electron microscopy results

primarily from the processing of pre-RNA and the assembly of ribosomal subunits.

Small Nucleolar RNAs Assist in Processing Pre-rRNAs

Ribosomal subunit assembly, maturation, and export to the cytoplasm are best understood in the yeast *S. cerevisiae*. However, nearly all the proteins and RNAs involved are highly conserved in multicellular eukaryotes, where the fundamental aspects of ribosome biosynthesis are likely to be the same. As we have seen with pre-mRNAs, nascent pre-rRNA transcripts are immediately bound by proteins, forming pre-ribosomal ribonucleoprotein particles (pre-rRNPs). Cleavage of the pre-rRNA does not begin until transcription of the pre-rRNA is nearly complete. In yeast, it takes approximately 6 minutes for a pre-rRNA to be transcribed. Once transcription is complete, the rRNA is cleaved, and bases and riboses are modified in about 10 seconds. In a rapidly growing yeast cell, ~40 pairs of ribosomal subunits are synthesized, processed, and transported to the cytoplasm every second. This extremely high rate of ribosome synthesis despite the seemingly long period required to transcribe a pre-rRNA is possible because pre-rRNA genes are packed with RNA polymerase I molecules transcribing the same gene simultaneously (see Figure 9-42) and because there are

100–200 such genes on chromosome XII, the yeast nucleolar organizer.

The primary transcript of ~6.6 kb is cut in a series of cleavage and exonucleolytic steps that ultimately yield the mature rRNAs found in ribosomes (Figure 9-44). During processing, pre-rRNA is also extensively modified, mostly by methylation of the 2′-hydroxyl group of specific riboses and conversion of specific uridine residues to pseudouridine. Virtually all of these modifications occur in the most conserved core structure of the ribosome, which is directly involved in protein synthesis. The positions of the specific sites of 2′-*O*-methylation and pseudouridine formation are determined by approximately 150 different small nucleolus- restricted RNA species, called **small nucleolar RNAs (snoRNAs)**, which hybridize transiently to pre-rRNA molecules. Like the snRNAs that function in pre-mRNA processing, snoRNAs associate with proteins, forming ribonucleoprotein particles called *snoRNPs*. One class of more than 40 snoRNPs (box C/D containing snoRNAs, see Figure 9-45a) positions a methyltransferase enzyme near methylation sites in the pre-mRNA. The multiple different box C/D snoRNAs direct methylation at multiple sites through a similar mechanism. They share common sequence and structural features, including the C and D box sequences (Figure 9-45a) and are bound by a common set of proteins. One or two regions of each of these snoRNAs are precisely complementary to sites on the pre-rRNA and direct the methyltransferase to specific riboses in the hybrid region (see Figure

9-45a). A second major class of snoRNPs (box H/ACA containing snoRNAs, Figure 9-45b) positions the enzyme that converts uridine to pseudouridine by rotation of the pyrimidine ring (Figure 9-45c). Bases on either side of the modified uridine in the pre-rRNA base-pair with bases in the bulge of a stem in the H/ACA snoRNAs, leaving the uridine to be modified bulged out of the helical double-stranded region, like the branch-point A bulges out in pre-mRNA spliceosomal splicing (see Figure 9-9d). Other modifications of pre-rRNA nucleotides, such as adenine dimethylation, are carried out by specific proteins without the assistance of guiding snoRNAs.

FIGURE 9-44 rRNA processing. Endoribonucleases that make internal cleavages are represented as scissors. Exoribonucleases that digest from one end, either $5'$ or $3'$, are shown as Pac-Men. Most $2'$-O-ribose methylation (CH_3) and generation of pseudouridines in the rRNAs occurs following the initial cleavage at the $3'$ end, before the initial cleavage at the $5'$ end. Proteins and snoRNPs known to participate in these steps are indicated. See J. Venema and D. Tollervey, 1999, *Ann. Rev. Genetics* **33**:261.

FIGURE 9-45 snoRNP-directed modification of pre-rRNA. (a) SnoRNAs called *box C/D snoRNAs* are involved in ribose 2′-O-methylation. Sequences in these snoRNAs hybridize to multiple different regions in the pre-rRNA, directing methylation at the indicated sites. (b) Box H/ACA snoRNAs fold into two stem loops with internal single-stranded bulges in the stems. Pre-rRNA hybridizes to the single-stranded bulges, demarcating a site of pseudouridylation. (c) Conversion from uridine to pseudouridine directed by the box H/ACA snoRNAs of part (b). See T. Kiss, 2001, *EMBO J.* **20**:3617. Part (b) from U. T. Meier, 2005, *Chromosoma* **114**:1.

The U3 snoRNA is assembled into a large snoRNP containing ~72 proteins called the *small subunit (SSU) processome*, which specifies cleavage at site A_0, the initial cut near the 5′ end of the pre-rRNA (see Figure 9-44). The processome helps to fold the 6.6-kb pre-rRNA into a structure required for the multiple cleavage events that follow transcription of the primary pre-rRNA transcript. U3 snoRNA base-pairs with an upstream region of the pre-rRNA to specify the location of the cleavage. The processome is thought to form the "5′ knob" visible in electron micrographs of pre-rRNPs (see Figure 9-

42). Base pairing of other snoRNPs specify additional cleavage reactions that remove transcribed spacer regions. The first cleavage to initiate processing of the 5.8S and 25S rRNAs of the large subunit is performed by RNase MRP, a complex of nine proteins with an RNA. Once cleaved from pre-rRNAs, these sequences are degraded by the same exosome-associated $3' \rightarrow 5'$ nuclear exonuclease that degrades introns spliced from pre-mRNAs. Nuclear $5' \rightarrow 3'$ exoribonucleases (Rat1; Xrn1) also remove some regions of $5'$ spacer.

Some snoRNAs are expressed from their own promoters by RNA polymerase II or III. Remarkably, however, the large majority of snoRNAs are processed from spliced-out introns of genes encoding functional mRNAs for proteins involved in ribosome synthesis or translation. Some snoRNAs are processed from introns spliced from apparently nonfunctional mRNAs. The genes encoding these mRNAs seem to exist only to express snoRNAs from excised introns.

Unlike 18S, 5.8S, and 28S genes, 5S rRNA genes are transcribed by RNA polymerase III in the nucleoplasm outside the nucleolus. With only minor additional processing to remove nucleotides at the $3'$ end, 5S rRNA diffuses to the nucleolus, where it assembles with the pre-rRNA precursor and remains associated with the region that is cleaved into the precursor of the large ribosomal subunit.

Most of the ribosomal proteins of the small 40S ribosomal subunit associate with the nascent pre-rRNA during transcription (Figure 9-46). Cleavage of the full-length pre-rRNA in the 90S RNP precursor releases a pre-40S particle that requires only a few more remodeling steps, that is gain or loss of associated proteins, base modifications, and changes in conformation, before it is transported to the cytoplasm, as diagrammed in Figure 9-46. Once the pre-40S particle leaves the nucleolus (purple in Figure 9-46), it traverses the nucleoplasm (blue) quickly and is exported through nuclear pore complexes (NPCs) to the cytoplasm (tan), as discussed below. Final maturation of the small ribosomal subunit occurs in the cytoplasm: exonucleolytic processing of the 20S rRNA into mature small subunit 18S rRNA by the cytoplasmic $5' \rightarrow 3'$ exoribonuclease Xrn1 and the dimethylation of two adjacent adenines near the $3'$ end of 18S rRNA by the cytoplasmic enzyme Dim1.

FIGURE 9-46 Ribosomal subunit assembly. Ribosomal proteins and RNAs in the maturing small and large ribosomal subunits are depicted in blue, with a shape similar to the icons for the mature subunits in the cytoplasm. Other factors that associate transiently with the maturing subunits are depicted in different colors, as shown in the key. See H. Tschochner and E. Hurt, 2003, *Trends Cell Biol.* **13**:255.

In contrast to the pre-40S particle, the precursor of the large subunit requires considerably more remodeling through many more transient interactions with nonribosomal proteins before it is sufficiently mature for export to the cytoplasm. Consequently, it takes a considerably longer period for the maturing 60S subunit to exit the nucleus (30 minutes compared to 5 minutes for export of the 40S subunit in cultured human cells). Multiple RNA helicases and

small G proteins are associated with the maturing pre-60S subunits. Some RNA helicases are necessary to dislodge the snoRNPs that base-pair perfectly with pre-rRNA over up to 30 base pairs. Other RNA helicases may function in the disruption of protein-RNA interactions. The requirement for so many GTPases suggests that there are many quality-control checkpoints in the assembly and remodeling of the large subunit RNP, where one step must be completed before a GTPase is activated to allow the next step to proceed. Members of the AAA ATPase family also bind transiently. This class of proteins is often involved in large molecular movements and may be required to fold the complex, large rRNA into the proper conformation. Some steps in 60S subunit maturation occur in the nucleoplasm (Figure 9-46, blue), during passage from the nucleolus to nuclear pore complexes. Much remains to be learned about the complex, fascinating, and essential remodeling processes that occur during formation of the ribosomal subunits.

The large ribosomal subunit is one of the largest structures to pass through the nuclear pore complexes. Maturation of the large subunit in the nucleoplasm leads to the generation of binding sites for a nuclear export adapter called *Nmd3*. Nmd3 is bound by the nuclear transporter Exportin 1 (also called *Crm1*). This is another quality-control step, because only correctly assembled subunits can bind Nmd3 and be exported. The small subunit of the mRNP exporter (NXT1) also becomes associated with the nearly mature large ribosomal subunit. These nuclear transporters permit diffusion of

the large subunit through the central channel of the NPC, which is filled with a cloud of unstructured protein domains that extend from the structured parts of proteins that line the wall of the channel (see Chapter 13). Several additional subunits that form the walls of the NPC central channel are also required for ribosomal subunit export and may have additional functions specific for this task. The dimensions of ribosomal subunits (~25–30 nm in diameter) and the central channel of the NPC are comparable, so passage may not require distortion of either the ribosomal subunit or the channel. Final maturation of the large subunit in the cytoplasm includes removal of these export factors. As for the export of most macromolecules from the nucleus, including tRNAs and pre-miRNAs (but not most mRNPs), ribosome subunit export requires the function of a small G protein called *Ran*, as discussed in Chapter 13.

Self-Splicing Group I Introns Were the First Examples of Catalytic RNA

During the 1970s, all the pre-rRNA genes of the protozoan *Tetrahymena thermophila* were discovered to contain an intron, indicating that splicing is required to produce mature rRNA in these organisms. In 1982, in vitro studies showing that the pre-rRNA was spliced at the correct sites in the absence of any protein provided

the first indication that RNA can function as a catalyst, like protein enzymes.

A whole raft of self-splicing sequences were subsequently found in pre-rRNAs from other single-celled organisms, in mitochondrial and chloroplast pre-rRNAs, in several pre-mRNAs from certain *Escherichia coli* bacteriophages, and in some bacterial tRNA primary transcripts. The self-splicing sequences in all these precursors, referred to as *group I introns*, use guanosine as a cofactor and can fold by internal base pairing to juxtapose closely the two exons that must be joined. As discussed earlier, certain mitochondrial and chloroplast pre-mRNAs and tRNAs contain a second type of self-splicing intron, designated *group II*.

The splicing mechanisms used by group I introns, group II introns, and spliceosomes are generally similar, involving two transesterification reactions, which require no input of energy (Figure 9-47). Structural studies of the group I intron from *Tetrahymena* pre-rRNA combined with mutational and biochemical experiments revealed that the RNA folds into a precise three-dimensional structure that, like protein enzymes, contains deep grooves for binding substrates and solvent-inaccessible regions that function in catalysis. The group I intron functions like a metalloenzyme to precisely orient the atoms that participate in the two transesterification reactions adjacent to catalytic Mg^{2+} ions. Considerable evidence now indicates that splicing by group II

introns and by snRNAs in the spliceosome also involves bound catalytic Mg^{2+} ions. In both the group I and II self-splicing introns, RNA functions as a **ribozyme**, an RNA sequence with catalytic ability. As discussed above, spliceosomal splicing is also catalyzed by Mg^{2+} ions held in the proper positions by U6 snRNA and its interactions with U1 and U5 snRNAs (see Figure 9-14c), but only with considerable help from multiple proteins that also shape the catalytic site and help bind and release substrates.

FIGURE 9-47 Splicing mechanisms in group I and group II self-splicing introns and spliceosome-catalyzed splicing of pre-mRNA. The intron is shown in gray, the exons to be joined in red. In group I introns, a guanosine cofactor (G) that is not part of the RNA chain associates with the active site. The 3′-hydroxyl group of this guanosine participates in a transesterification reaction with the phosphate at the 5′ end of the intron; this reaction is analogous to that involving the 2′-hydroxyl groups of branch-site A's in group II introns and pre-mRNA introns spliced in spliceosomes (see Figure 8-8). The subsequent

transesterification that links the 5′ and 3′ exons is similar in all three splicing mechanisms. Note that spliced-out group I introns are linear structures, unlike the branched intron products in the other two cases. See P. A. Sharp, 1987, *Science* **235**:769.

Pre-tRNAs Undergo Extensive Modification in the Nucleus

Mature cytosolic tRNAs, which average 75–80 nucleotides in length, are produced from larger precursors (pre-tRNAs) synthesized by RNA polymerase III in the nucleoplasm. Mature tRNAs also contain numerous modified bases that are not present in tRNA primary transcripts. Cleavage and base modification occur during processing of all pre-tRNAs; some pre-tRNAs also are spliced during processing. All of these processing and modification events occur in the nucleus.

A 5′ sequence of variable length that is absent from mature tRNAs is present in all pre-tRNAs (Figure 9-48). This occurs because the 5′ end of mature tRNAs is generated by an endonucleolytic cleavage specified by the tRNA three-dimensional structure rather than the start site of transcription. These extra 5′ nucleotides are removed by ribonuclease P (RNase P), a ribonucleoprotein endonuclease. Studies with *E. coli* RNase P indicate that at high Mg^{2+} concentrations the RNA component alone can recognize and cleave *E. coli* pre-tRNAs. The RNase P polypeptide increases the rate of

cleavage by the RNA, allowing it to proceed at physiological Mg^{2+} concentrations. A comparable RNase P functions in eukaryotes.

FIGURE 9-48 Changes that occur during the processing of tyrosine pre-tRNA. A 14-nucleotide intron (blue) in the anticodon loop is removed by splicing. A 16-nucleotide sequence (green) at the 5′ end is cleaved by RNase P. U residues at the 3′ end are replaced by the CCA sequence (red) found in all mature tRNAs. Numerous bases in the stem-loops are converted to characteristic modified bases (yellow). Not all pre-tRNAs contain introns that are spliced out during processing, but they all undergo the other types of changes shown here. D = dihydrouridine; Ψ = pseudouridine.

About 10 percent of the bases in pre-tRNAs are modified enzymatically during processing. Three classes of base modifications have been described (Figure 9-48): (1) U residues at the 3′ end of pre-tRNA are replaced with a CCA sequence. The CCA

sequence is found at the 3′ end of all tRNAs and is required for their charging by amino-acyl-tRNA synthetases during protein synthesis. This step in tRNA synthesis likely functions as a quality-control point, since only properly folded tRNAs are recognized by the CCA addition enzyme. (2) Methyl and isopentenyl groups are added to the heterocyclic ring of purine bases, and the 2′-OH groups in the ribose of specific residues are methylated. (3) Specific uridines are converted to dihydrouridine, pseudouridine, or ribothymidine residues. The functions of these base and ribose modifications are not well understood, but since they are highly conserved, they probably function in protein synthesis.

As shown in Figure 9-48, the pre-tRNA expressed from the yeast tyrosine tRNA (tRNATyr) gene contains a 14-base intron that is not present in mature tRNATyr. Some other eukaryotic tRNA genes and some archaeal tRNA genes also contain introns. The introns in nuclear pre-tRNAs are shorter than those in pre-mRNAs and lack the consensus splice-site sequences found in pre-mRNAs (see Figure 9-7c). Pre-tRNA introns are also clearly distinct from the much longer self-splicing group I and group II introns found in chloroplast and mitochondrial pre-rRNAs. The mechanism of pre-tRNA splicing differs greatly from spliceosomal and self-splicing group I and group II intron splicing (see Figure 9-47). First, splicing of pre-tRNAs is catalyzed by proteins, not by RNAs. Second, a pre-tRNA intron is excised in one step that entails simultaneous cleavage at both ends of the intron. Finally, hydrolysis of GTP and ATP is required to join

the two tRNA halves generated by cleavage on either side of the intron.

After pre-tRNAs are processed in the nucleoplasm, the mature tRNAs are transported to the cytoplasm through nuclear pore complexes by Exportin-t, a transporter (see Chapter 13) dedicated to the nuclear export of tRNAs. In the cytoplasm, tRNAs are passed between aminoacyl-tRNA synthetases, elongation factors, and ribosomes during protein synthesis (Chapter 5). Thus tRNAs generally are associated with proteins and spend little time free in the cell, as is also the case for mRNAs and rRNAs.

KEY CONCEPTS OF SECTION 9.5

Processing of rRNA and tRNA

- A large precursor pre-rRNA (13.7 kb in humans) transcribed by RNA polymerase I undergoes cleavage, exonucleolytic digestion, and base modifications to yield mature 28S, 18S, and 5.8S rRNAs, which associate with ribosomal proteins into ribosomal subunits.
- Transcription and processing of pre-rRNA occur in the nucleolus. The 5S rRNA component of the large ribosomal subunit is synthesized in the nucleoplasm by RNA polymerase III.
- Approximately 150 snoRNAs, associated with proteins in snoRNPs, base-pair with specific sites in pre-rRNA, where they direct ribose methylation, modification of uridine to pseudouridine, and cleavage at specific sites during rRNA processing in the nucleolus.
- Group I and group II self-splicing introns, and probably snRNAs in spliceosomes, all function as ribozymes, or catalytically active RNA sequences, that carry out splicing by analogous transesterification reactions requiring bound Mg^{2+} ions (see Figure 9-47).
- Pre-tRNAs synthesized by RNA polymerase III in the nucleoplasm are processed by removal of the $5'$-end sequence, addition of CCA to the $3'$ end, and modification of

multiple internal bases (see Figure 9-48).

- Some pre-tRNAs contain a short intron that is removed by a protein-catalyzed mechanism distinct from the splicing mechanisms used by pre-mRNAs and self-splicing introns.
- All species of RNA molecules are associated with proteins in various types of ribonucleoprotein particles, both in the nucleus and after export to the cytoplasm.

9.6 Nuclear Bodies Are Functionally Specialized Nuclear Domains

High-resolution visualization of plant- and animal-cell nuclei by electron microscopy and by staining with fluorescently labeled antibodies has revealed specialized nuclear domains, called **nuclear bodies**. These domains are not surrounded by membranes. Nonetheless, they are regions of high concentrations of specific proteins and RNAs that form distinct, often roughly spherical structures within the nucleus (Figure 9-49). The most prominent nuclear bodies are nucleoli, the sites of ribosomal subunit synthesis and assembly discussed earlier. Several other types of nuclear bodies also have been described in structural studies.

Experiments with fluorescently labeled nuclear proteins have shown that the nucleus is a highly dynamic environment, with rapid diffusion of proteins through the nucleoplasm. Proteins associated with nuclear bodies are often also observed at lower concentrations in the nucleoplasm outside the nuclear bodies, and fluorescence studies indicate that they diffuse in and out of the nuclear bodies. Based on these measurements of molecular mobility in living cells, nuclear bodies can be mathematically modeled as the expected steady state for diffusing proteins that interact with sufficient affinity to form self-organized regions of high concentrations of specific proteins, but with low enough affinity for each other to be able to diffuse in and out of the structure. This is similar to the

situation for transcriptional condensates discussed in Chapter 8 (Figure 8-38) and cytoplasmic ribonuclear protein particles involved in localization of mRNAs associated with motor proteins that "walk" on actin filaments and microtubules (see Figures 9-40b and 9-41). In electron micrographs, these structures appear to be a heterogeneous, spongelike network of interacting components. We discuss a few examples of nuclear bodies here.

Cajal Bodies

Cajal bodies are ~0.2–1 μm spherical structures that have been observed in large nuclei for more than a century (Figure 9-49a). Current research indicates that like nucleoli, Cajal bodies are centers of RNP-complex assembly, in this case for spliceosomal snRNPs and other nuclear RNPs. Like rRNAs, snRNAs undergo specific modifications, such as the conversion of specific uridine residues to pseudouridine and addition of methyl groups to the 2′-hydroxyl groups of specific riboses. These post-transcriptional modifications are important for the proper assembly and function of snRNPs in pre-mRNA splicing. These modifications occur in Cajal bodies, where they are directed by a class of snoRNA-like guide RNA molecules called *scaRNAs* (small Cajal body–associated RNAs). There is also evidence that the Cajal body is the site of reassembly of the U4/U6/U5 tri-snRNP complexes required for pre-mRNA splicing from the free U4, U5, and U6 snRNPs released during the removal of each intron (see Figure 9-13). Since Cajal bodies also contain a high

concentration of the U7 snRNP involved in the specialized 3′-end processing of the major histone mRNAs, it is likely that this process also occurs in Cajal bodies, as may the assembly of the telomerase RNP.

Nuclear Speckles

Nuclear speckles were observed using fluorescently labeled antibodies to snRNP proteins and other proteins involved in pre-mRNA splicing, as approximately 25–50 irregular, amorphous structures 0.5–2 μm in diameter that are distributed through the nucleoplasm of vertebrate cells (Figure 9-49c, d). Since speckles are not located at sites of co-transcriptional pre-mRNA splicing, which are associated closely with chromatin, they are thought to be storage regions for snRNPs and proteins involved in pre-mRNA splicing that are released into the nucleoplasm when required.

FIGURE 9-49 Examples of nuclear bodies. (a, b) Cajal bodies and nucleoli in a HeLa cell nucleus. (a, *left*) DIC image showing four nucleoli and three Cajal bodies (arrowheads). Scale bar = 10 μm. (a, *right*) The same nucleus immunostained with antibodies against coilin (green) and fibrillarin (red). The three Cajal bodies appear yellow because they stain with both antibodies. The nucleoli stain only for fibrillarin. Fibrillarin is the methyltransferase for $2'$-O-methylation of rRNA in the nucleoli and snRNAs in the Cajal Bodies. (b) Transmission electron microscopy of nuclear bodies in a Xeopus oocyte nucleus. These extraordinarily large nuclei are larger than in most vertebrate cells. A nucleolus and a histone body with an associated speckle were relatively close to each other in this oocyte nucleus, and consequently were observed in the same electron micrograph. Scale bar = 1 μm. (c) HeLa cell stained with DAPI (blue), antibody to SC35 (red), a splicing factor stored in nuclear bodies called "speckles," and antibody to PSPC1, a protein found in nuclear bodies called "paraspeckles" (white arrows) because they are most often observed close to speckles. Scale bar = 10 μm. (d) PML-nuclear bodies in an H1299 cell (a lung canrcinoma cell line) nucleus. DNA was stained with DAPI (blue) and PML-nuclear bodies were immunostained with antibody to the major protein in these bodies, PML. Scale bar = 1 μm.

Nuclear Paraspeckles

Paraspeckles are composed of RNPs formed by the interaction between a long nonprotein-coding RNA species (lncRNA), NEAT1, and members of the DBHS (*Drosophila* Behavior Human Splicing) family of proteins, P54NRB/NONO, PSPC1, and PSF/SFPQ. Paraspeckles are critical to the control of gene expression through the nuclear retention of RNA containing double-stranded RNA regions that have been subjected to adenosine-to-inosine editing. In this way, they may function in the incompletely understood mRNA quality-control mechanisms that operate in the nucleus.

Promyelocytic Leukemia (PML) Nuclear Bodies

The PML gene was originally discovered when chromosomal translocations within the gene were observed in the leukemic cells of patients with the rare disease promyelocytic leukemia (PML). When antibodies specific for the PML protein were used in immunofluorescence microscopy studies, the protein was found to localize to ∼10–30 roughly spherical regions 0.3–1 μm in diameter in the nuclei of mammalian cells. Multiple functions have been proposed for these PML nuclear bodies, but a consensus is emerging that they function as sites for the assembly and modification of protein complexes involved in DNA repair and the induction of

apoptosis. For example, the important p53 tumor suppressor protein appears to be post-translationally modified by phosphorylation and acetylation in PML nuclear bodies in response to DNA damage, increasing its ability to activate the expression of DNA-damage response genes. PML nuclear bodies are also required for cellular defenses against DNA viruses that are induced by interferons, proteins secreted by virus-infected cells and T-lymphocytes involved in the immune response (see Chapter 24).

PML nuclear bodies are also sites of protein post-translational modification through the addition of a small, ubiquitin-like protein called *SUMO1* (small ubiquitin-like moiety-1), which can control the activity and subcellular localization of the modified protein. Many transcriptional activators are inhibited when they are sumoylated, and mutation of their site of sumoylation increases their activity in stimulating transcription. These observations indicate that PML nuclear bodies are involved in a mechanism of transcriptional repression that remains to be thoroughly understood.

Nucleolar Functions in Addition to Ribosomal Subunit Synthesis

The first nuclear bodies to be observed, the nucleoli, have specialized regions of substructure (Figure 9-49b) that are dedicated to functions other than ribosome biogenesis. There is evidence that

immature SRP ribonucleoprotein complexes involved in protein secretion and ER membrane insertion (Chapter 13) are assembled in nucleoli and then exported to the cytoplasm, where their final maturation takes place. The Cdc14 protein phosphatase that regulates processes in the final stages of mitosis is sequestered in nucleoli until chromosomes have been properly segregated into daughter cells (Chapter 19). Also, a tumor-suppressor protein called *ARF*, which is involved in the regulation of the protein encoded by the most frequently mutated gene in human cancers, *p53*, is sequestered in nucleoli and released in response to DNA damage (Chapter 25). In addition, heterochromatin often forms on the surface of nucleoli (see Figure 7-29a), suggesting that proteins associated with nucleoli also participate in the formation of this repressing chromatin structure.

KEY CONCEPT OF SECTION 9.6

Nuclear Bodies Are Functionally Specialized Nuclear Domains

- Nuclear bodies are functionally specialized regions in the nucleus where interacting proteins form self-organized structures. Many of these bodies, including the nucleolus, are regions of assembly of RNP complexes.

Review the Concepts

1. Describe three types of post-transcriptional regulation of protein-coding genes.
2. True or false? The CTD is responsible for mRNA-processing steps that are specific for mRNA and not for other forms of RNA. Explain why you chose true or false.
3. There are a number of conserved sequences found in an mRNA that dictate where splicing occurs. Where are these sequences found relative to the exon-intron junctions? What is the significance of these sequences in the splicing process? One of these important regions is the branch-point A found in the intron. What is the role of the branch-point A in the splicing process, and can this be accomplished with the OH group on either the 2′ or the 3′ carbon?
4. What are the differences between hnRNAs, snRNAs, miRNAs, siRNAs, and snoRNAs?
5. What are the mechanistic similarities between group II intron self-splicing and spliceosomal splicing? What is the evidence that there may be an evolutionary relationship between the two?
6. You obtain the sequence of a gene containing 10 exons, 9 introns, and a 3′ UTR containing a polyadenylation

consensus sequence. The fifth intron also contains a polyadenylation site. To test whether both polyadenylation sites are used, you isolate mRNA and find a longer transcript from muscle tissue and a shorter transcript from all other tissues. Speculate about the mechanism involved in the production of these different transcripts.

7. RNA editing is a common process in the mitochondria of trypanosomes and plants as well as in chloroplasts, and in rare cases it occurs in higher eukaryotes. What is RNA editing, and what benefit does it demonstrate in the documented example of ApoB in humans?
8. Because DNA is found in the nucleus, transcription is a nuclear-localized process. Ribosomes responsible for protein synthesis are found in the cytoplasm. Why is hnRNP trafficking to the cytoplasm restricted to the nuclear pore complexes?
9. A protein complex in the nucleus is responsible for transporting mRNA molecules into the cytoplasm. Describe the proteins that form this exporter. What two protein groups are probably behind the mechanism involved in the directional movement of the mRNP and exporter into the cytosol?
10. RNA knockdown has become a powerful tool in the arsenal of methods used to repress gene expression. Briefly describe how gene expression can be knocked down.
11. Speculate about why plants deficient in Dicer activity show increased sensitivity to infection by RNA viruses.

12. mRNA stability is a key regulator of protein levels in a cell. Briefly describe the three mRNA degradation pathways. Suppose that a yeast cell has a mutation in the DCP1 gene, resulting in decreased uncapping activity. Would you expect to see a change in the P bodies found in this mutant cell?
13. mRNA localization now appears to be a common phenomenon. What benefit does mRNA localization have for a cell? What is the evidence that some mRNAs are directed to accumulate in specific subcellular locations?

CHAPTER 10

Biomembrane Structure

Ramón Andrade, 3Dciencia/Science Source.

Molecular model of a lipid bilayer with embedded membrane proteins. Integral membrane proteins have distinct exoplasmic, cytosolic, and membrane-spanning domains. Shown here are portions of the insulin receptor, which regulates cell metabolism.

OUTLINE

10.1 The Lipid Bilayer: Composition and Structural Organization
10.2 Membrane Proteins: Structure and Basic Functions
10.3 Phospholipids, Sphingolipids, and Cholesterol: Synthesis and Intracellular Movement

Membranes participate in many aspects of cell structure and function. The **plasma membrane** defines the cell and separates the inside from the outside. In eukaryotes, membranes also define intracellular organelles such as the nucleus, mitochondrion, and lysosome. These *biomembranes* all have the same basic architecture: a phospholipid bilayer in which proteins are embedded (Figure 10-1). By preventing the unassisted movement of most water-soluble substances across the membrane, the phospholipid bilayer serves as a permeability barrier, helping to maintain the characteristic differences between the inside and the outside of the cell or organelle. In turn, the embedded proteins endow the membrane with specific functions, such as regulated transport of substances from one side to the other. Each type of cellular membrane has its own set of proteins that allow it to carry out many different functions.

FIGURE 10-1 Fluid mosaic model of biomembranes. A bilayer of phospholipids about 3–4 nm thick provides the basic architecture of all cellular membranes; membrane proteins give each cellular membrane its unique set of functions. Individual phospholipids can move laterally and spin within the plane of the membrane, giving the membrane a fluidlike consistency similar to that of olive oil. Noncovalent interactions between phospholipids, and between phospholipids and proteins, lend strength and resilience to the membrane, while the hydrophobic core of the bilayer prevents the unassisted movement of water-soluble substances from one side to the other. Integral membrane proteins (transmembrane proteins) span the bilayer and often form dimers and higher order oligomers. Lipid-anchored proteins are tethered to one leaflet by a covalently attached hydrocarbon chain. Peripheral membrane proteins associate with the membrane primarily by specific noncovalent interactions with integral membrane proteins or membrane lipids. See D. Engelman, 2005, *Nature* **438**:578–580.]

Prokaryotes, the simplest and smallest cells, are about 1–2 μm in length and are usually surrounded by a single plasma membrane; in most cases, they contain no internal membrane-limited subcompartments (see Figure 1-12). However, this single plasma

membrane contains hundreds of different types of proteins that are integral to the function of the cell. Some of these proteins catalyze ATP synthesis and initiation of DNA replication, for instance. Others include the many types of **membrane transport proteins** that enable specific ions, sugars, amino acids, and vitamins to cross the otherwise impermeable phospholipid bilayer to enter the cell and that allow specific metabolic products to exit. **Receptor proteins** in the plasma membrane are proteins that allow the cell to recognize chemical signals present in its environment and adjust its metabolism or pattern of gene expression in response. *Peripheral membrane proteins*, discussed in Section 10.2, associate with the membrane primarily by specific noncovalent interactions with integral membrane proteins or membrane lipids.

Eukaryotes also have a plasma membrane studded with many different proteins that perform a variety of functions, including membrane transport, cell signaling, and connecting cells into tissues. In addition, eukaryotic cells — which are generally much larger than prokaryotes — have a variety of internal membrane-bounded organelles (see Figure 1-13). Each type of organelle membrane has a unique complement of proteins that enable it to carry out its characteristic cellular functions, such as ATP generation (in mitochondria) and DNA synthesis (in the nucleus). Many plasma membrane proteins also bind components of the **cytoskeleton**, a dense network of protein filaments that crisscrosses the cytosol to provide mechanical support for cellular membranes.

These interactions are essential for the cell to assume and maintain its specific shape and for many types of cell movements.

Despite playing a structural role in cells, membranes are not rigid structures. They can bend and flex in three dimensions while still maintaining their integrity, in part because of the abundant noncovalent interactions that hold the lipids and proteins together. Moreover, there is considerable mobility of individual lipids and proteins within the plane of the membrane. According to the *fluid mosaic model* of biomembranes, first proposed by researchers in the 1970s, the phospholipid bilayer behaves in some respects like a two-dimensional fluid, with individual lipid molecules able to move past one another as well as spin in place. Such fluidity and flexibility not only allow organelles to assume their typical shapes but also confer on the membrane the dynamic property that enables membrane budding and fusion/fission, as occurs when viruses enter a cell or are released from an infected cell (Figure 10-2a). Internal cellular membranes of the Golgi complex bud into vesicles in the cytosol (Figure 10-2b) and then fuse with other membranes to transport their contents from one organelle to another (see Chapter 14).

FIGURE 10-2 Eukaryotic cellular membranes are dynamic structures. (a) An electron micrograph of the plasma membrane of an HIV-infected cell, showing HIV particles budding into the culture medium. As the virus core buds from the cell, it becomes enveloped by a membrane, derived from the cell's plasma membrane, that contains specific viral proteins. (b) Stacked membranes of the

Golgi complex with budding vesicles. Note the irregular shape and curvature of these membranes.

We begin our examination of biomembranes by considering their lipid components. These molecules not only affect membrane shape and function but also help anchor proteins to the membrane, modify membrane protein activities, and transduce signals to the cytoplasm. We then consider the structure of membrane proteins. Many of these proteins have large segments that are embedded in the hydrocarbon core of the phospholipid bilayer, and we focus on the principal classes of such transmembrane proteins. Finally, we consider how lipids such as phospholipids and cholesterol are synthesized in cells and distributed to their many membranes and organelles.

10.1 The Lipid Bilayer: Composition and Structural Organization

In Chapter 2, we learned that phospholipids are the principal building blocks of biomembranes. There are multiple types of phospholipids, but the most common phospholipids in membranes are the phosphoglycerides (see Figure 2-20). All phospholipids are **amphipathic** molecules, meaning that they consist of two segments with very different chemical properties: a fatty acid–based (fatty acyl) hydrocarbon "tail" that is **hydrophobic** ("water fearing") and partitions away from water, and a polar "head group" that is strongly **hydrophilic** ("water loving") and tends to interact with water molecules. The interactions of phospholipids with one another and with water largely determine the structure of biomembranes.

Besides phospholipids, biomembranes contain smaller amounts of other amphipathic lipids, such as glycolipids and cholesterol, which contribute to membrane function in important ways. We first consider the structure and properties of pure phospholipid bilayers and then discuss the composition and behavior of natural cellular membranes. Then we consider how the precise lipid composition of a given membrane influences its physical properties.

Phospholipids Spontaneously Form Bilayers

The amphipathic nature of phospholipids, which governs their interactions, is critical to the structure of biomembranes. When a suspension of phospholipids is mechanically dispersed (e.g., by ultrasound, or "sonication") in an aqueous solution, the phospholipids aggregate into one of three structures: spherical **micelles** or **liposomes**, or sheet-like **phospholipid bilayers** that are two molecules thick (Figure 10-3). The type of structure formed by pure phospholipids or a mixture of phospholipids in the absence of added proteins depends on several factors, including the length of the fatty acyl chains in the hydrophobic tails, their degree of saturation (i.e., the number of C—C and C=C bonds), and temperature. In all three structures, the hydrophobic effect (see Chapter 2) causes the fatty acyl chains to aggregate and exclude water molecules from the core of the structure. Micelles are rarely formed from natural phospholipids, whose fatty acyl chains are generally too bulky to fit into the interior of a micelle. Micelles are formed, however, if one of the two fatty acyl chains that make up the tail of a phospholipid is removed by hydrolysis to form a lysophospholipid, as occurs upon treatment with the enzyme phospholipase. In aqueous solutions, common detergents and soaps form micelles that behave like the balls in tiny ball bearings, thus giving soap solutions their slippery feel and lubricating properties.

FIGURE 10-3 The bilayer structure of biomembranes. (a) Electron micrograph of a thin section through an erythrocyte membrane stained with osmium tetroxide. The characteristic "railroad track" appearance of the membrane indicates the presence of two polar layers, consistent with the bilayer structure of phospholipid membranes. (b) Schematic interpretation of the phospholipid bilayer. Polar groups face outward to shield the hydrophobic fatty acyl tails from water. The hydrophobic effect and van der Waals interactions between the fatty acyl tails drive the assembly of the bilayer (see Chapter 2). (c) Cross-sectional views of two other structures formed by dispersal of phospholipids in water. A spherical micelle has a hydrophobic interior composed entirely of fatty acyl chains; a spherical liposome consists of a phospholipid bilayer surrounding an aqueous center. (d) Under certain circumstances, lipids can assume yet other forms of organization. Shown here is the cubic phase of lipids, a highly regular recurring structure that has helped the formation of crystals of membrane proteins that were otherwise difficult to crystallize.

Phospholipid mixtures of the composition present in cells spontaneously form a symmetric phospholipid bilayer. Each phospholipid layer in this lamellar structure is called a *leaflet*. The hydrophobic fatty acyl chains in each leaflet minimize their contact with water by aligning themselves tightly together in the center of the bilayer, forming a hydrophobic core that is about 3–4 nm thick (see Figure 10-3b). The close packing of these nonpolar tails is stabilized by van der Waals interactions between the hydrocarbon chains. Ionic and hydrogen bonds stabilize the interactions of the polar head groups with one another and with water. Electron microscopy of thin sections of cells stained with osmium tetroxide, which binds strongly to the polar head groups of phospholipids, shows the bilayer structure (see Figure 10-3a). A cross section of a single membrane stained with osmium tetroxide looks like a

railroad track: two thin dark lines (the stained head group complexes) with a uniform light space of about 2 nm between them (the hydrophobic tails).

A phospholipid bilayer can be of almost unlimited size — from micrometers (μm) to millimeters (mm) in length or width — and can contain tens of millions of phospholipid molecules. The phospholipid bilayer is the basic structural unit of nearly all biological membranes. Its hydrophobic core prevents most water-soluble substances from crossing from one side of the membrane to the other. Although biomembranes contain other molecules (e.g., cholesterol, glycolipids, proteins), it is the phospholipid bilayer that separates two aqueous solutions and acts as a permeability barrier. The lipid bilayer thus defines cellular compartments and separates the cell's interior from the outside world.

The three structures mentioned above are not the only forms that lipids can assume in an aqueous environment. Unusual configurations of lipids have been instrumental in enforcing order on otherwise difficult-to-crystallize membrane proteins, including G protein–coupled receptors, enabling crystallographic analysis of membrane proteins in a true lipid environment (Figure 10-3d).

Phospholipid Bilayers Form a Sealed Compartment Surrounding an Internal

Aqueous Space

Phospholipid bilayers can be generated in the laboratory by simple means, using either chemically pure phospholipids or lipid mixtures of the composition found in cellular membranes (Figure 10-4). Such synthetic bilayers possess three important properties. First, they are virtually impermeable to water-soluble (hydrophilic) solutes, which do not readily diffuse across the bilayer. These solutes include salts, sugars, and most other small hydrophilic molecules — including water itself. The second property of a bilayer is its stability. The hydrophobic and van der Waals interactions between the fatty acyl chains maintain the integrity of the interior of the bilayer structure. Even though the exterior aqueous environment may vary widely in ionic strength and pH, the bilayer has the strength to retain its characteristic architecture. Third, all synthetic phospholipid bilayers can spontaneously form sealed compartments in which the aqueous space on the inside is separated from the exterior environment. An edge of a phospholipid bilayer, as depicted in Figure 10-3b, with the hydrocarbon core of the bilayer exposed to an aqueous solution, would be unstable; the exposed fatty acyl chains would be in an energetically much more stable state if they were not adjacent to water molecules but rather surrounded by other fatty acyl chains. Thus, in an aqueous solution, sheets of phospholipid bilayers spontaneously seal their edges, forming a spherical bilayer that encloses an aqueous central compartment. The liposome depicted in Figure 10-3c is an example of such a structure viewed in cross section. Phospholipid bilayers can even be formed and

immobilized on a solid support such as a microscope slide, which allows the incorporation of membrane proteins whose behavior in the plane of the membrane can then be studied by various microscopical techniques.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 10-4 Formation and study of pure phospholipid bilayers. *Top:* A preparation of biological membranes is treated with an organic solvent, such as a mixture of chloroform and methanol (3:1), which selectively solubilizes the phospholipids and cholesterol. Proteins and carbohydrates remain in an insoluble residue. The solvent is removed by evaporation. *Bottom left:* If the extracted materials are mechanically dispersed in water, they spontaneously form a liposome, shown in cross section, with an internal aqueous compartment. *Bottom right:* A planar bilayer, also shown in cross section, can form over a small hole in a partition separating two aqueous phases; such a system can be used to study the physical properties of bilayers, such as their permeability to solutes.

This physical chemical property of a phospholipid bilayer has important implications for cellular membranes: no membrane in a cell can have an edge with exposed hydrocarbon fatty acyl chains. All membranes form closed compartments, similar in basic architecture to liposomes. Because all cellular membranes enclose an entire cell or an internal compartment, they have an *internal face* (the surface oriented toward the interior of the compartment) and an *external face* (the surface presented to the environment). More commonly, we designate the two surfaces of a cellular membrane as the **cytosolic face** and the **exoplasmic face**. This nomenclature is useful in highlighting the topological equivalence of the faces in different membranes, as diagrammed in Figures 10-5 and 10-6. For example, the exoplasmic face of the plasma membrane is directed away from the cytosol, toward the extracellular space or external environment, and defines the outer limit of the cell. The cytosolic face of the plasma membrane faces the cytosol.

FIGURE 10-5 The faces of cellular membranes. The plasma membrane, a single bilayer, encloses the cell. In this highly schematic representation, internal cytosol (tan) and external environment (white) define the cytosolic (red) and exoplasmic (gray) faces of the bilayer. Vesicles and some organelles have a single membrane, and their internal aqueous space (white) is topologically equivalent to the outside of the cell. Three organelles — the nucleus, mitochondrion, and chloroplast (not shown) — are enclosed by two membranes separated by a small intermembrane space. The exoplasmic faces of the inner and outer membranes around these organelles border the intermembrane space between them. For simplicity, the hydrophobic membrane interior is not indicated in this diagram.

FIGURE 10-6 The faces of cellular membranes are conserved during membrane budding and fusion. Red membrane surfaces are cytosolic faces; gray membrane surfaces are exoplasmic faces. During endocytosis, a segment of the plasma membrane buds inward toward the cytosol and eventually pinches off a separate vesicle. During this process, the cytosolic face of the plasma membrane remains facing the cytosol, and the exoplasmic face of the new vesicle membrane faces the vesicle lumen. During exocytosis, an intracellular vesicle fuses with the plasma membrane, and the lumen of the vesicle (exoplasmic face) connects with the extracellular medium. Proteins that span the membrane retain their asymmetric orientation during vesicle budding and fusion; in particular, the same segment always faces the cytosol.

Similarly for organelles and vesicles surrounded by a single membrane, the cytosolic face is directed toward the cytosol. The exoplasmic face is always directed away from the cytosol, and in this case it is on the inside of the organelle, in contact with the internal aqueous space, or *lumen*. The lumen of a vesicle is topologically

equivalent to the extracellular space, a concept most easily understood for vesicles that arise by invagination (endocytosis) of the plasma membrane. The external face of the plasma membrane becomes the internal face of the vesicle membrane, while in the vesicle the cytosolic face of the plasma membrane still faces the cytosol (see Figure 10-6).

Three organelles — the nucleus, mitochondrion, and chloroplast — are surrounded not by a single membrane, but by two. The exoplasmic surface of each membrane faces the space between the two membranes (the intermembrane space). This relationship can perhaps be best understood by reference to the *endosymbiont hypothesis*, discussed in Chapter 12, which posits that mitochondria and chloroplasts arose early in the evolution of eukaryotic cells by the engulfment of bacteria capable of oxidative phosphorylation or photosynthesis, respectively (see Figure 12-7). Gram-negative bacteria such as *Escherichia coli* are likewise surrounded by two membranes (see Figure 1-12).

Natural membranes from different cell types exhibit a variety of shapes, which complement a cell's function. The smooth, flexible surface of the erythrocyte plasma membrane allows the cell to squeeze through narrow blood capillaries (Figure 10-7). Some cells have a long, slender extension of the plasma membrane, called a **cilium** or **flagellum**, which beats in a whiplike manner (see Figure 1-15). This motion causes fluid to flow across the surface of a sheet of

cells or a sperm cell to swim toward an egg. The differing shapes and properties of biomembranes raise a key question in cell biology, namely, how the composition of biological membranes is regulated to establish and maintain the identity of the different membrane structures and membrane-limited compartments. We return to this question in Section 10.3 and in Chapter 14.

Omikron/Science Source.

FIGURE 10-7 Variation in biomembranes in different cell types. A smooth, flexible membrane covers the surface of the discoid erythrocyte cell, as seen in this scanning electron micrograph.

Biomembranes Contain Three Principal Classes of Lipids

The term *phospholipid* refers to any amphipathic lipid with a phosphate-based head group and a two-chain hydrophobic tail. A typical biomembrane is not composed of phospholipids alone, but actually contains three classes of amphipathic lipids: phosphoglycerides, sphingolipids, and sterols, which differ in their chemical structures, abundance, and functions in the membrane (Figure 10-8). While all phosphoglycerides are phospholipids, only certain sphingolipids are, and no sterols are.

FIGURE 10-8 Three classes of membrane lipids. (a) Most phosphoglycerides are derivatives of glycerol 3-phosphate (red), which contains two esterified fatty acyl chains that constitute the hydrophobic "tail" and a polar "head group" esterified to the phosphate. The fatty acids can vary in length and be saturated (no double bonds) or unsaturated (one, two, or three

double bonds). In phosphatidylcholine (PC), the head group is choline. Also shown are the molecules attached to the phosphate group in three other common phosphoglycerides: phosphatidylethanolamine (PE), phosphatidylserine (PS), and phosphatidylinositol (PI). Plasmalogens contain one fatty acyl chain attached to glycerol by an ester linkage and one attached by an ether linkage; they contain the same head groups as other phosphoglycerides. (b) Sphingolipids are derivatives of sphingosine (red), an amino alcohol with a long hydrocarbon chain. Various fatty acyl chains are connected to sphingosine by an amide bond. The sphingomyelins (SM), which contain a phosphocholine head group, are phospholipids. Other sphingolipids are glycolipids in which a single sugar residue or branched oligosaccharide is attached to the sphingosine backbone. For instance, the simple glycolipid glucosylcerebroside (GlcCer) has a glucose head group. (c) The major sterols in animals, fungi, and plants differ slightly in structure, but all serve as key components of cellular membranes. The basic structure of sterols is a four-ring hydrocarbon (yellow). Like other membrane lipids, sterols are amphipathic. The single hydroxyl group is equivalent to the polar head group in other lipids; the conjugated ring and short hydrocarbon chain form the hydrophobic tail. See H. Sprong, P. van der Sluijs, and G. van Meer, 2001, *Nature Rev. Mol. Cell Biol.* **2**:504–513.

Phosphoglycerides, the most abundant class of phospholipids in most membranes are derivatives of glycerol 3-phosphate (see Figure 10-8a). A typical phosphoglyceride molecule consists of a hydrophobic tail composed of two fatty acyl chains esterified to the two hydroxyl groups in glycerol phosphate and a polar head group attached to the phosphate group. The structure comprising the glycerol moiety and the two fatty acyl chains is referred to as a *diacylglycerol*. The two fatty acyl chains may differ in the number of carbons that they contain (commonly 16 or 18) and their degree of saturation (0, 1, or 2 double bonds). A phosphoglyceride is classified according to the nature of its head group. In phosphatidylcholines, the most abundant phospholipids in the plasma membrane, the

head group consists of choline, a positively charged alcohol, esterified to the negatively charged phosphate. In other phosphoglycerides, an OH-containing molecule such as ethanolamine, serine, or the sugar derivative inositol is linked to the phosphate group. In the case of the inositol head group, the hydroxyl groups may be further modified with phosphates, yielding a class of phospholipids called *phosphoinositides*. The phosphoinositides fulfill an important function in signal transduction, as discussed in Chapters 15 and 16. The negatively charged phosphate group and the positively charged groups or hydroxyl groups on the head group interact strongly with water. At neutral pH, some phosphoglycerides (e.g., phosphatidylcholine and phosphatidylethanolamine) carry no net electric charge, whereas others (e.g., phosphatidylinositol and phosphatidylserine) carry a single net negative charge. Nonetheless, the polar head groups in all these phospholipids can pack together into the characteristic bilayer structure. When phospholipases act on phosphoglycerides, they produce lysophospholipids, which lack one of the two acyl chains. Lysophospholipids are not only important signaling molecules, released from cells and recognized by specific receptors; their presence can also affect the physical properties of the membranes in which they reside.

The *plasmalogens* are a group of phosphoglycerides that contain one fatty acyl chain attached to carbon 2 of glycerol by an ester linkage and one long hydrocarbon chain attached to carbon 1 of glycerol by

an ether (C—O—C) rather than an ester linkage. Plasmalogens are particularly abundant in human brain and heart tissue. The greater chemical stability of the ether linkage in plasmalogens compared with the ester linkage, and the subtle differences in three-dimensional structure between plasmalogens and other phosphoglycerides, may have as yet unrecognized physiological significance.

A second class of membrane lipids is the **sphingolipids**. All these compounds are derived from sphingosine, an amino alcohol with a long hydrocarbon chain. Sphingolipids contain a long-chain fatty acid attached in amide linkage to the sphingosine amino group (see Figure 10-8b). Like phosphoglycerides, some sphingolipids have a phosphate-based polar head group. In sphingomyelin, the most abundant sphingolipid, phosphocholine is attached to the terminal hydroxyl group of sphingosine (see Figure 10-8b; SM). Thus sphingomyelin is a phospholipid, and its overall structure is quite similar to that of phosphatidylcholine. Sphingomyelins are similar in shape to phosphoglycerides and can form mixed bilayers with them. Other sphingolipids are amphipathic **glycolipids** whose polar head groups are sugars that are not linked to the tails via a phosphate group (so they are not phospholipids). Glucosylcerebroside, the simplest glycosphingolipid, contains a single glucose unit attached to sphingosine. In the complex glycosphingolipids called *gangliosides*, one or two branched sugar chains (oligosaccharides) containing sialic acid groups are attached

to sphingosine. Glycolipids constitute 2–10 percent of the total lipid content of plasma membranes; they are most abundant in nervous tissue.

Cholesterol and its analogs constitute the third important class of membrane lipids, the *sterols*. The basic structure of sterols is a four-ring isoprenoid-based hydrocarbon. The structures of the principal yeast sterol (ergosterol) and plant phytosterols (e.g., stigmasterol) differ slightly from that of cholesterol, the major animal sterol (see Figure 10-8c). The small differences in the biosynthetic pathways and structures of fungal and animal sterols are the basis of most antifungal drugs currently in use. Cholesterol, like the two other sterols, has a hydroxyl substituent on one ring. Although cholesterol is almost entirely hydrocarbon in composition, it is amphipathic because its hydroxyl group can interact with water. Because it lacks a phosphate-based head group, it is not a phospholipid. Cholesterol is especially abundant in the plasma membranes of mammalian cells but is absent from most prokaryotic and all plant cells. As much as 30–50 percent of the lipids in plant plasma membranes consist of certain steroids unique to plants. Between 50 and 90 percent of the cholesterol in most mammalian cells is present in the plasma membrane and associated vesicles. Cholesterol and other sterols are too hydrophobic to form a bilayer structure on their own. Instead, at the concentrations found in natural membranes, these sterols must intercalate between phospholipid molecules to be incorporated into biomembranes. When so intercalated, sterols

provide structural support to membranes, preventing too close a packing of the phospholipids' acyl chains to maintain a significant measure of membrane fluidity and at the same time conferring the necessary rigidity required for mechanical support. Some of these effects can be highly local, as in the case of lipid rafts, discussed below.

In addition to its structural role in membranes, cholesterol is the precursor for several important bioactive molecules. They include *bile acids*, which are made in the liver and help emulsify dietary fats for digestion and absorption in the intestines; steroid hormones produced by endocrine cells (e.g., adrenal gland, ovary, testes); and vitamin D produced in the skin and kidneys. Another critical function of cholesterol is its covalent addition to Hedgehog protein, a key signaling molecule in embryonic development (see Chapter 16).

Most Lipids and Many Proteins Are Laterally Mobile in Biomembranes

In the two-dimensional plane of a bilayer, thermal motion permits lipid molecules to rotate freely around their long axes and to diffuse laterally within each leaflet. Because such movements are lateral or rotational, the fatty acyl chains remain in the hydrophobic interior of the bilayer. In both natural and artificial membranes, a typical

lipid molecule exchanges places with its neighbors in a leaflet about 10^7 times per second and diffuses several micrometers per second at 37 °C. These diffusion rates indicate that the bilayer is 100 times more viscous than water — about the same as the viscosity of olive oil. Even though lipids diffuse more slowly in the bilayer than in an aqueous solvent, a membrane lipid could diffuse the length of a typical bacterial cell (1 μm) in only 1 second and the length of an animal cell in about 20 seconds. When artificial pure phospholipid membranes are cooled below 37 °C, the lipids can undergo a *phase transition* from a liquid-like (fluid) state to a gel-like (semisolid) state, analogous to the liquid-solid transition when molten butter solidifies upon cooling or liquid water freezes (Figure 10-9). Below the phase-transition temperature, the rate of diffusion of the lipids drops precipitously. At usual physiological temperatures, the hydrophobic interior of natural membranes generally has a low viscosity and a fluidlike consistency, in contrast to the gel-like consistency observed at lower temperatures.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 10-9 Gel-like and fluidlike forms of the phospholipid bilayer. *Top:* Depiction of gel-to-fluid transition. Phospholipids with long saturated fatty acyl chains tend to assemble into a highly ordered, gel-like bilayer in which there is little overlap of the nonpolar tails in the two leaflets. Heat disorders the nonpolar tails and induces a transition from a gel to a fluid within a temperature range of only a few degrees. As the chains become disordered, the bilayer also decreases in thickness. *Bottom:* Molecular models of phospholipid monolayers in gel-like and fluidlike states, as determined by molecular dynamics calculations.

[Data from H. Heller, M. Schaefer, and K. Schulten, 1993, *J. Phys. Chem.* **97**:8343.]

In pure lipid bilayers (i.e., in the absence of protein), phospholipids and sphingolipids rotate and move laterally, but they do not usually spontaneously migrate, or flip-flop, from one leaflet to the other. The energetic barrier is too high; migration would require moving

the polar head group from its aqueous environment through the hydrocarbon core of the bilayer to the aqueous solution on the other side. Special membrane proteins discussed in Chapter 11 are required to flip membrane lipids and other polar molecules from one leaflet to the other.

The lateral movements of specific plasma-membrane proteins and lipids can be quantified by a technique called *fluorescence recovery after photobleaching (FRAP)*. Phospholipids containing a fluorescent substituent are used to monitor lipid movement. For proteins, a fragment of a monoclonal antibody (see Chapter 23) that is specific for the exoplasmic domain of the desired protein and that has only a single antigen-binding site is tagged with a fluorescent dye (alternatively, a genetic fusion of the desired protein with fluorescent green protein can accomplish the same goal). With this method, described in Figure 10-10, the rate at which membrane molecules move — the diffusion coefficient — can be determined, as well as the proportion of the molecules that are laterally mobile.

EXPERIMENTAL FIGURE 10-10 Fluorescence recovery after photobleaching (FRAP) experiments can quantify the lateral movement of proteins and lipids within the plasma membrane. (a) Experimental protocol. Step **1**: Cells are first labeled with a fluorescent reagent that binds uniformly to a specific membrane lipid or protein. Genetic fusion of the desired protein with green fluorescent protein (GFP) can accomplish the same goal. Step **2**: A laser light is then focused on a small area of the cell surface, irreversibly bleaching the bound reagent (or GFP) and thus reducing the fluorescence in the illuminated area. Step **3**: In time, the fluorescence of the bleached patch increases as unbleached fluorescent surface molecules diffuse into it and bleached ones diffuse outward. The extent of recovery of fluorescence in the bleached patch is proportional to the fraction of labeled molecules that are mobile in the membrane. (b) Results of a FRAP experiment with human hepatoma cells treated with a fluorescent antibody specific for the asialoglycoprotein receptor protein. The finding that 50 percent of the fluorescence returned to the bleached area indicates that 50 percent of the receptor molecules in the illuminated membrane patch were mobile and 50 percent were immobile. Because the rate of fluorescence recovery is proportional to the rate at which labeled molecules move into the bleached region, the diffusion coefficient of a protein or lipid in the membrane can be calculated from such data.

[Data from Y. I. Henis et al., 1990, *J. Cell Biol.* **111**:1409.]

The results of FRAP studies with fluorescence-labeled phospholipids have shown that in fibroblast plasma membranes, all phospholipids are freely mobile over distances of about 0.5 μm, but most cannot diffuse over much longer distances. These findings suggest that protein-rich regions of the plasma membrane about 1 μm in diameter separate lipid-rich regions containing the bulk of the membrane phospholipids. Phospholipids are free to diffuse within such regions, but not from one lipid-rich region to an adjacent one. Furthermore, the rate of lateral diffusion of lipids in the plasma membrane is nearly an order of magnitude slower than in pure phospholipid bilayers: diffusion constants of 10^{-8} cm^2 per second and 10^{-7} cm^2 per second are characteristic of the plasma membrane and a pure phospholipid bilayer, respectively. This difference suggests that lipids may be tightly but not irreversibly bound to certain integral proteins in some membranes, as indeed has recently been demonstrated (see the discussion of annular phospholipids below).

Lipid Composition Influences the Physical Properties of Membranes

A typical cell contains many different types of membranes, each with unique properties derived from its particular mix of lipids and proteins. The data in Table 10-1 illustrate the variation in lipid composition in different biomembranes. Several phenomena

contribute to these differences. For instance, the relative abundances of phosphoglycerides and sphingolipids differ between membranes in the endoplasmic reticulum (ER), where phospholipids are synthesized, and the Golgi complex, where sphingolipids are synthesized. The proportion of sphingomyelin as a percentage of total membrane lipid phosphorus is about six times as high in Golgi membranes as it is in ER membranes. In other cases, the movement of membranes from one cellular compartment to another can selectively enrich certain membranes in lipids such as cholesterol. In responding to differing environments throughout an organism, different types of cells generate membranes with differing lipid compositions. In the cells that line the intestinal tract, for example, the membranes that face the harsh environment in which dietary nutrients are digested have a sphingolipid-to-phosphoglyceride-to-cholesterol ratio of 1:1:1, rather than the 0.5:1.5:1 ratio found in cells subject to less stress. The relatively high concentration of sphingolipids in these intestinal membranes may increase their stability because of extensive hydrogen bonding by the free −OH group in the sphingosine moiety (see Figure 10-8).

TABLE 10-1 • Major Lipid Components of Selected Biomembranes

	Composition (mol %)			
Source/Location	**PC**	**PE + PS**	**SM**	**Cholesterol**
Plasma membrane (human erythrocytes)	21	29	21	26
Myelin membrane (human	16	37	13	34

neurons)				
Plasma membrane (mung bean)	47	43	0	0
Inner mitochondrial membrane (cauliflower)	42	38	0	0
Outer mitochondrial membrane (cauliflower)	47	27	0	0
Plasma membrane *(E. coli)*	0	85	0	0
Endoplasmic reticulum membrane (rat)	60	25	3	7
Golgi membrane (rat)	51	26	8	13
Inner mitochondrial membrane (rat)	40	37	2	7
Outer mitochondrial membrane (rat)	54	31	2	11
Primary leaflet location	Exoplasmic	Cytosolic	Exoplasmic	Both

PC = phosphatidylcholine; PE = phosphatidylethanolamine; PS = phosphatidylserine, SM = sphingomyelin.

The degree of bilayer fluidity depends on lipid composition, the structure of the phospholipid hydrophobic tails, and temperature. As already noted, van der Waals interactions and the hydrophobic effect cause the nonpolar tails of phospholipids to aggregate. Long,

saturated fatty acyl chains have the greatest tendency to aggregate, packing tightly together into a gel-like state. Phospholipids with short fatty acyl chains, which have less surface area and therefore fewer van der Waals interactions, form more fluid bilayers. Likewise, the kinks in cis-unsaturated fatty acyl chains (see Chapter 2) result in their forming less stable van der Waals interactions with other lipids, and hence more fluid bilayers, than do straight saturated chains, which can pack more tightly together.

Cholesterol is important in maintaining the appropriate fluidity of natural membranes, a property that appears to be essential for normal cell growth and reproduction. Cholesterol restricts the random movement of phospholipid head groups at the outer surfaces of the leaflets, but its effect on the movement of long phospholipid tails depends on its concentration. At the cholesterol concentrations normally present in the plasma membrane, the interaction of the steroid ring with the long hydrophobic tails of phospholipids tends to immobilize those lipids and thus decreases biomembrane fluidity. It is this property that can help organize the plasma membrane into discrete subdomains of unique lipid and protein composition. At lower cholesterol concentrations, however, the steroid ring separates and disperses phospholipid tails, causing the inner regions of the membrane to become slightly more fluid.

The lipid composition of a bilayer also influences its thickness, which in turn may influence the distribution of other membrane components, such as proteins, in a particular membrane. It has

been argued that relatively short transmembrane segments of certain Golgi-resident enzymes (glycosyltransferases) are an adaptation to the lipid composition of the Golgi membrane and contribute to the retention of these enzymes in the Golgi apparatus. The results of biophysical studies on artificial membranes demonstrate that sphingomyelin associates into a more gel-like and thicker bilayer than phosphoglycerides do (Figure 10-11a). Cholesterol and other molecules that decrease membrane fluidity also increase membrane bilayer thickness. Because sphingomyelin tails are already optimally stabilized, the addition of cholesterol has no effect on the thickness of a sphingomyelin bilayer.

FIGURE 10-11 Effect of lipid composition on bilayer thickness and curvature. (a) A pure sphingomyelin (SM) bilayer is thicker than one formed from a phosphoglyceride such as phosphatidylcholine (PC). Cholesterol has a lipid-ordering effect on phosphoglyceride bilayers that increases their thickness, but it does not affect the thickness of the more ordered SM bilayer. (b) Phospholipids such as PC have a cylindrical shape and form essentially flat monolayers, whereas those with smaller head groups, such as phosphatidylethanolamine (PE), have a conical shape. (c) A bilayer enriched

with PC in the exoplasmic leaflet and with PE in the cytosolic face, as in many plasma membranes, would have a natural curvature.

[Information from H. Sprong et al., 2001, *Nat. Rev. Mol. Cell Biol.* **2**:504–513.]

Another property dependent on the lipid composition of a bilayer is its curvature, which depends on the relative sizes of the polar head groups and nonpolar tails of its constituent phospholipids. Lipids with long tails and large head groups are cylindrical in shape; those with small head groups are cone-shaped (Figure 10-11b). As a result, bilayers composed of cylindrical lipids are relatively flat, whereas those containing large numbers of cone-shaped lipids form curved bilayers (Figure 10-11c). This effect of lipid composition on bilayer curvature may play a role in the formation of highly curved membranes, such as sites of viral budding (see Figure 10-2) and of formation of internal vesicles from the plasma membrane (see Figure 10-6), and in specialized stable membrane structures such as microvilli. Several proteins, including *reticulons* (RTNs in vertebrates; reticulon-like proteins or RTNLs in other eukaryotes) bind to the surface of a phospholipid bilayer and cause the membrane to curve; such proteins are important in formation of transport vesicles that bud from a donor membrane (see Chapter 14).

Lipid Composition Is Different in the Exoplasmic and Cytosolic Leaflets

A characteristic of all biomembranes is an asymmetry in lipid composition across the bilayer. Although most phospholipids are present in both membrane leaflets, some are more abundant in one or the other leaflet. For instance, in plasma membranes from human erythrocytes and Madin-Darby canine kidney (MDCK) cells grown in culture, almost all the sphingomyelin and phosphatidylcholine, both of which form less fluid bilayers, are found in the exoplasmic leaflet. In contrast, phosphatidylethanolamine, phosphatidylserine, and phosphatidylinositol, which form more fluid bilayers, are preferentially located in the cytosolic leaflet. Because phosphatidylserine and phosphatidylinositol carry a net negative charge, the stretch of amino acids on the cytosolic face of a membrane protein with a single transmembrane segment is often enriched in positively charged (Lys, Arg) residues in close proximity to the transmembrane segment (this distribution of charged amino acids is referred to as the "inside positive" rule). This segregation of lipids across the bilayer may influence membrane curvature (see Figure 10-11c). Unlike particular phospholipids, cholesterol is relatively evenly distributed in both leaflets of cellular membranes.

The relative abundances of a particular phospholipid in the two leaflets of a plasma membrane can be determined experimentally on the basis of the susceptibility of phospholipids to hydrolysis by **phospholipases**, enzymes that cleave the ester bonds via which acyl chains and head groups are connected to the lipid molecule (Figure 10-12). When added to the external medium, phospholipases cannot

cross the membrane, and thus they cleave off the head groups of only those lipids present in the exoplasmic face; phospholipids in the cytosolic leaflet are resistant to hydrolysis because the enzymes cannot penetrate to the cytosolic face of the plasma membrane.

FIGURE 10-12 Specificity of phospholipases. Each type of phospholipase cleaves one of the susceptible bonds shown in red. The glycerol carbon atoms are indicated by small numbers. In intact cells, only phospholipids in the exoplasmic leaflet of the plasma membrane are cleaved by phospholipases in the surrounding medium. Phospholipase C, a cytosolic enzyme, cleaves certain phospholipids in the cytosolic leaflet of the plasma membrane.

How the asymmetric distribution of phospholipids in membrane leaflets arises and is maintained is still unclear. As noted, in pure bilayers, phospholipids do not spontaneously migrate, or flip-flop, from one leaflet to the other. In part, the asymmetry in phospholipid distribution may reflect where these lipids are synthesized in the ER and Golgi. Sphingomyelin is synthesized on the luminal (exoplasmic) face of the Golgi, which becomes the exoplasmic face of the plasma membrane. In contrast, phosphoglycerides are synthesized on the cytosolic face of the ER membrane, which is topologically equivalent to the cytosolic face of the plasma membrane (see Figure 10-5). Clearly, however, this explanation does not account for the preferential location of phosphatidylcholine (a phosphoglyceride) in the exoplasmic leaflet. Movement of this phosphoglyceride, and perhaps others, from one leaflet to the other in some natural membranes is most likely catalyzed by ATP-powered transport proteins called *flippases*, which are discussed in Chapter 11.

The preferential location of lipids on one face of the bilayer is necessary for a variety of membrane-based functions. For example, the head groups of all phosphorylated forms of phosphatidylinositol (see Figure 10-8b; PI), an important source of second messengers, face the cytosol. Stimulation of many cell-surface receptors by their corresponding ligands results in activation of the cytosolic enzyme phospholipase C, which can then hydrolyze the bond within PI

connecting the phosphoinositols to the diacylglycerol. As we will see in Chapter 15, both water-soluble phosphoinositols and membrane-embedded diacylglycerol participate in intracellular signaling pathways that affect many aspects of cellular metabolism. Phosphatidylserine, too, is normally most abundant in the cytosolic leaflet of the plasma membrane. In the initial stages of platelet stimulation by serum, phosphatidylserine is briefly translocated to the exoplasmic face, presumably by a flippase enzyme, where it activates enzymes participating in blood clotting. When cells die, lipid asymmetry is no longer maintained, and phosphatidylserine, normally enriched in the cytosolic leaflet, is increasingly found in the exoplasmic one. This increased exposure is detected experimentally by use of a labeled version of annexin V, a protein that specifically binds to phosphatidylserine, to measure the onset of programmed cell death (apoptosis). As discussed in Chapter 22, the increased exposure of phosphatidylserine on dying or dead cells is recognized by phagocytic cells, which initiate engulfment of such apoptotic bodies and thus ensure timely and safe disposal of cell remnants.

Cholesterol and Sphingolipids Cluster with Specific Proteins in Membrane Microdomains

Membrane lipids are not randomly distributed (evenly mixed) in each leaflet of a bilayer. One hint that lipids may be organized within the leaflets was the discovery that the lipids remaining after the extraction (solubilization) of plasma membranes with non-ionic detergents such as Triton X-100 predominantly contain two species: cholesterol and sphingomyelin. Because these two lipids are found in more ordered, less fluid bilayers, researchers hypothesized that they form microdomains, termed **lipid rafts**, surrounded by other, more fluid phospholipids that are more readily extracted by non-ionic detergents. (We discuss more fully the role of ionic and non-ionic detergents in extracting membrane proteins in Section 10.2.)

Some biochemical and microscopic evidence supports the existence of lipid rafts, which in natural membranes are typically 50 nm in diameter. Rafts can be disrupted by methyl-β-cyclodextrin, which specifically extracts cholesterol from membranes, or by antibiotics such as filipin that sequester cholesterol into aggregates within the membrane. Such findings indicate the importance of cholesterol in maintaining the integrity of lipid rafts. These raft fractions, defined by their insolubility in non-ionic detergents, contain a subset of plasma-membrane proteins, many of which are implicated in sensing extracellular signals and transmitting them into the cytosol. Because raft fractions are enriched in glycolipids, an important tool for microscopic visualization of raft-type structures in intact cells is the use of fluorescently labeled cholera toxin, a protein that specifically binds to certain gangliosides. By bringing many key proteins into close proximity and stabilizing their interactions, lipid

rafts may facilitate signaling by cell-surface receptors and the subsequent activation of cytosolic events. However, much remains to be learned about the structure and biological function of lipid rafts. The unique properties of some of the raft-associated lipids, such as glycolipids, may permit interactions of their tails across the hydrophobic core and help organize lipids of the cytosolic leaflet in the formation of signaling platforms.

Cells Store Excess Lipids in Lipid Droplets

Lipid droplets are vesicular structures, composed of triglycerides and cholesterol esters, that originate from the ER and serve a lipid-storage function. When a cell's supply of lipids exceeds the immediate need for membrane construction, excess lipids are relegated to these lipid droplets, readily visualized in live cells by staining with a lipophilic dye such as Congo red. Feeding cells with oleic acid, a type of fatty acid, enhances lipid droplet formation. Lipid droplets are not only storage compartments for triglycerides and cholesterol esters, but may also serve as platforms for storage of proteins targeted for degradation. The biogenesis of lipid droplets starts with delamination of the lipid bilayer of the ER through insertion of triglycerides and cholesterol esters that are more hydrophobic than cholesterol itself (Figure 10-13). The lipid "lens" continues to grow by insertion of more lipid, until finally a lipid

droplet is hatched by scission from the ER. The resulting cytoplasmic droplet is thereby surrounded by a phospholipid monolayer. The details of lipid droplet biogenesis, as well as its functions, remain to be defined more clearly.

FIGURE 10-13 Lipid droplets form by budding and scission from the ER membrane. Lipid droplet formation begins with the accumulation of cholesterol esters and triglycerides within the hydrophobic core of the lipid bilayer. The resulting delamination of the two lipid monolayers causes a "lens" to form, the further growth of which creates a spherical droplet that is then released by scission at the neck. The newly formed droplet is surrounded by a lipid monolayer, derived from the cytosolic leaflet of the ER membrane.

KEY CONCEPTS OF SECTION 10.1

The Lipid Bilayer: Composition and Structural Organization

- Membranes are crucial to cell structure and function. The eukaryotic cell is demarcated from the external environment by the plasma membrane and organized into membrane-limited subcompartments (organelles and vesicles).
- The phospholipid bilayer, the basic structural unit of all biomembranes, is a lipid sheet two molecules thick, with hydrophilic faces and a hydrophobic core that is impermeable to water-soluble molecules and ions. Proteins embedded in the bilayer endow the membrane with specific functions (see Figure 10-1).
- Phospholipids spontaneously form bilayers and sealed compartments surrounding an aqueous space (see Figure 10-3).
- As bilayers, all biological membranes have an internal (cytosolic) face and an external (exoplasmic) face (see Figure 10-5). Some organelles, such as *E. coli*, are surrounded by two, rather than one, membrane bilayers.
- The primary lipid components of biomembranes are phosphoglycerides, sphingolipids, and sterols such as cholesterol. The term "phospholipid" applies to any amphipathic lipid molecule with a fatty acyl hydrocarbon tail and a phosphate-based polar head group (see Figure 10-8).

- Biomembranes can undergo phase transitions from fluidlike to gel-like states depending on the temperature and the composition of the membrane (see Figure 10-9).
- Most lipids and many proteins are laterally mobile in biomembranes (see Figure 10-10).
- Different cellular membranes vary in lipid composition (see Table 10-1). Phospholipids and sphingolipids are asymmetrically distributed in the two leaflets of the bilayer, whereas cholesterol is fairly evenly distributed in both leaflets.
- Natural biomembranes generally have a viscous consistency with fluidlike properties. In general, membrane fluidity is decreased by sphingolipids and cholesterol and increased by phosphoglycerides. The lipid composition of a membrane also influences its thickness and curvature (see Figure 10-11).
- Lipid rafts are microdomains containing cholesterol, sphingolipids, and certain membrane proteins that form in the plane of the bilayer. These lipid-protein aggregates might facilitate signaling by certain plasma-membrane receptors.
- Lipid droplets are storage vesicles for lipids, originating in the ER (see Figure 10-13).

10.2 Membrane Proteins: Structure and Basic Functions

Membrane proteins are defined by their location within or at the surface of a phospholipid bilayer. Although every biological membrane has the same basic bilayer structure, in which the proteins associated with a particular membrane are responsible for its distinctive activities. The kinds and amounts of proteins associated with biomembranes vary depending on cell type and subcellular location. For example, the inner mitochondrial membrane is 76 percent protein, but the myelin membrane that surrounds nerve axons is only 18 percent. The high phospholipid content of myelin allows it to electrically insulate the nerve from its environment, as we discuss in Chapter 23. The importance of membrane proteins is evident from the finding that approximately a third of all yeast genes encode a membrane protein. The relative abundance of genes for membrane proteins is even greater in multicellular organisms, in which they have additional functions in cell adhesion and in communication between different cell types (cell-cell interactions). Indeed, of the ~20,000 genes in the human genome, ~7000 encode membrane proteins.

The lipid bilayer presents a distinctive two-dimensional hydrophobic environment for membrane proteins. Some proteins contain segments that are embedded within the hydrophobic core of the phospholipid bilayer; other proteins are associated with the

exoplasmic or cytosolic leaflet of the bilayer. Protein domains on the extracellular surface of the plasma membrane generally bind to extracellular molecules, including external signaling proteins, ions, and small metabolites (e.g., glucose, fatty acids), as well as proteins on other cells or in the external environment. Segments of proteins within the plasma membrane perform multiple functions, such as forming the channels and pores through which molecules and ions move into and out of cells. These intramembrane segments also serve to organize multiple membrane proteins into larger assemblies within the plane of the membrane. Domains lying along the cytosolic face of the plasma membrane have a wide range of functions, from anchoring cytoskeletal proteins to the membrane to triggering intracellular signaling pathways or synthesis of ATP.

In many cases, the function of a membrane protein and the topology of its polypeptide chain in the membrane can be predicted on the basis of its similarity with other well-characterized proteins. In this section, we examine the characteristic structural features of membrane proteins and some of their basic functions. We describe the structures of several proteins to help you get a feel for how membrane proteins interact with membranes. More complete characterizations of the properties of various types of membrane proteins are presented in later chapters that focus on their structures and activities in the context of their cellular functions.

Proteins Interact with Membranes in Three Different Ways

Membrane proteins can be classified into three categories — integral, lipid-anchored, and peripheral — on the basis of their position with respect to the membrane (see Figure 10-1). **Integral membrane proteins**, also called *transmembrane proteins*, span a phospholipid bilayer and comprise three domains. The cytosolic and exoplasmic domains have hydrophilic exterior surfaces that interact with the aqueous environment on the cytosolic and exoplasmic faces of the membrane. These domains resemble segments of other water-soluble proteins in their amino acid composition and structure. In contrast, the membrane-spanning segments usually contain many hydrophobic amino acids whose side chains protrude outward and interact with the hydrophobic hydrocarbon core of the phospholipid bilayer. In all transmembrane proteins examined to date, the membrane-spanning domains consist of one or more α helices or of multiple β strands. We discuss the ribosomal synthesis and post-translational processing of soluble cytosolic proteins in Chapters 5 and 9; the process by which integral membrane proteins are inserted into membranes as part of their synthesis is discussed in Chapter 13.

Lipid-anchored membrane proteins are bound covalently to one or more lipid molecules. The hydrophobic tail of the attached lipid is embedded in one leaflet of the membrane and anchors the protein

to the membrane. The polypeptide chain itself does not enter the phospholipid bilayer.

Peripheral membrane proteins (see Figure 10-1) do not directly contact the hydrophobic core of the phospholipid bilayer. Instead, they are bound to the membrane either indirectly by interactions with integral or lipid-anchored membrane proteins or directly by interactions with lipid head groups. Peripheral proteins can be bound to either the cytosolic or the exoplasmic face of the plasma membrane. In addition to these proteins, which are closely associated with the bilayer, cytoskeletal filaments can be more loosely associated with the cytosolic face, usually through one or more peripheral adapter proteins. Such associations with the cytoskeleton provide support for various cellular membranes, helping to determine the cell's shape and mechanical properties, and play a role in the two-way communication between the cell interior and the exterior, as we explore in Chapter 17. Finally, peripheral proteins on the outer surface of the plasma membrane and the exoplasmic domains of integral membrane proteins are often attached to components of the extracellular matrix or to the cell walls surrounding bacterial and plant cells, providing a crucial interface between the cell and its environment.

Most Transmembrane Proteins Have Membrane-Spanning α Helices

Soluble proteins exhibit hundreds of distinct localized folded structures, or motifs (see Figure 3-7). In comparison, the repertoire of folded structures in the transmembrane domains of integral membrane proteins is quite limited, with the hydrophobic α helix predominating. Proteins containing membrane-spanning α-helical domains are stably embedded in membranes. This is due to energetically favorable hydrophobic and van der Waals interactions of the hydrophobic side chains in the domain with specific lipids and probably also because of ionic interactions with the polar head groups of the phospholipids.

A single α-helical domain is sufficient to incorporate an integral membrane protein into a membrane. However, many such proteins have more than one transmembrane α helix. Typically, a membrane-embedded α helix is composed of a continuous segment of 20–25 hydrophobic (uncharged) amino acids (see Figure 2-14). The predicted length of such an α helix (3.75 nm) is just sufficient to span the hydrocarbon core of a phospholipid bilayer. In many membrane proteins, these helices are perpendicular to the plane of the membrane, whereas in others, the helices traverse the membrane at an oblique angle. The hydrophobic side chains protrude outward from the helix and form van der Waals interactions with the fatty acyl chains in the bilayer. In contrast, the hydrophilic amide peptide bonds are in the interior of the α helix (see Figure 3-4); each carbonyl (C═O) group forms a hydrogen bond with the amide hydrogen atom of the amino acid four residues toward the C-

terminus of the helix. These polar groups are shielded from the hydrophobic interior of the membrane.

To help you get a better sense of the structures of proteins with α-helical domains, we will briefly discuss four different kinds of such proteins: glycophorin A, G protein–coupled receptors, aquaporins (water/glycerol channels), and the T-cell receptor for antigen.

Glycophorin A, the major protein in the erythrocyte plasma membrane, is a representative *single-pass* transmembrane protein, which contains only one membrane-spanning α helix (Figure 10-14a). The 23-residue membrane-spanning α helix is composed of amino acids with hydrophobic (uncharged) side chains, which interact with the fatty acyl chains in the surrounding bilayer. In cells, glycophorin A typically forms dimers: the transmembrane helix of one glycophorin A polypeptide associates with the corresponding transmembrane helix in a second glycophorin A to form a coiled-coil structure (Figure 10-14b). Such interactions of membrane-spanning α helices are a common mechanism for creating dimeric membrane proteins, and many membrane proteins form oligomers (two or more polypeptides bound together noncovalently) by interactions between their membrane-spanning helices.

FIGURE 10-14 Structure of glycophorin A, a typical single-pass transmembrane protein. (a) Diagram of dimeric glycophorin, showing its major sequence features and its relation to the membrane. The single 23-residue membrane-spanning α helix in each monomer is composed of amino acids with hydrophobic (uncharged) side chains (red and green spheres). By binding negatively charged phospholipid head groups, the positively charged arginine and lysine residues (blue spheres) near the cytosolic side of the helix help anchor glycophorin in the membrane. Both the extracellular and the cytosolic domains are rich in charged residues and polar uncharged residues; the extracellular domain is heavily glycosylated, with carbohydrate chains (green diamonds) attached to specific serine, threonine, and asparagine residues. (b) Molecular model of the transmembrane domain of dimeric glycophorin A corresponding to residues 73–96. The hydrophobic side chains of the α helix in one monomer are shown in pink; those of the other monomer, in green. Residues depicted as space-filling structures participate in van der Waals interactions that stabilize the coiled-coil dimer. Note how the hydrophobic side chains project outward from the helix, toward what would be the surrounding fatty acyl chains.

[Part (b) Data from K. R. MacKenzie, J. H. Prestegard, and D. M. Engelman, 1997, *Science* **276**:131, PDB ID 1afo.]

A large and important group of integral membrane proteins is defined by the presence of seven membrane-spanning α helices. This group includes the large family of G protein–coupled cell-surface receptors discussed in Chapter 15, many of which have been crystallized. One such *multipass* transmembrane protein of known structure is bacteriorhodopsin, a protein found in the membranes of certain photosynthetic bacteria; it illustrates the general structure of all these proteins (Figure 10-15a). Absorption of light by the retinal group covalently attached to this protein causes a conformational change in the protein that results in the pumping of protons from the cytosol across the bacterial membrane to the extracellular space. The proton concentration gradient thus generated across the membrane is used to synthesize ATP during photosynthesis (see Chapter 12). In the high-resolution structure of bacteriorhodopsin, the positions of all the individual amino acids, the retinal group, and the surrounding lipids are clearly defined. As might be expected, virtually all the amino acids on the exterior of the membrane-spanning segments of bacteriorhodopsin are hydrophobic, permitting energetically favorable interactions with the hydrocarbon core of the surrounding lipid bilayer.

FIGURE 10-15 Structural models of two multipass transmembrane proteins. (a) The seven hydrophobic α helices in bacteriorhodopsin (a photoreceptor in certain bacteria) traverse the lipid bilayer roughly perpendicular to the plane of the membrane. A retinal molecule (black) covalently attached to one helix absorbs light. The large class of G protein–coupled receptors in eukaryotic cells also has seven membrane-spanning α helices; their three-dimensional structure is similar to that of bacteriorhodopsin. (b) Two views of the glycerol channel Glpf, rotated 180° with respect to each other along an axis perpendicular to the plane of the membrane. Note the several membrane-spanning α helices that are at oblique angles, the two helices that penetrate only halfway through the membrane (purple with yellow arrows), and the one long membrane-spanning helix with a "break" or distortion in the middle (purple with yellow line). The glycerol molecule in the hydrophilic "core" is colored red. The protein structure was approximately positioned in the hydrocarbon core of the membrane by finding the most hydrophobic 3-μm slab of the protein perpendicular to the membrane plane.

[Part (a) Data from H. Luecke et al., 1999, *J. Mol. Biol.* **291**:899. Part (b) Data from J. Bowie, 2005, *Nature* **438**:581–589, PDB ID 1c3w; and D. Fu et al., 2000, *Science* **290**:481–486, PDB ID 1fx8.]

The aquaporins are a large family of highly conserved proteins that transport water, glycerol, and other hydrophilic molecules across biomembranes. They illustrate several aspects of the structure of multipass transmembrane proteins. Aquaporins are tetramers of

four identical subunits. Each of the four subunits has six membrane-spanning α helices, some of which traverse the membrane at oblique angles rather than perpendicularly. Because all aquaporins have similar structures, we will focus on one, the glycerol channel Glpf, whose structure has been especially well defined by x-ray diffraction studies (Figure 10-15b). This aquaporin has one long transmembrane helix with a bend in the middle, and more strikingly, there are two α helices that penetrate only halfway through the membrane. The N-termini of these helices face each other (yellow N's in the figure), and together they span the membrane at an oblique angle. Thus some membrane-embedded helices — and other, nonhelical, structures we will encounter later — do not traverse the entire bilayer. As we will see in Chapter 11, these short helices in aquaporins form part of the glycerol/water-selective pore in the middle of each subunit (see Figure 11-8). This structure highlights the considerable diversity in the ways membrane-spanning α helices interact with the lipid bilayer and with other segments of the protein.

The specificity of phospholipid-protein interactions is evident from the structure of a different aquaporin, aquaporin 0 (Figure 10-16). Aquaporin 0 is the most abundant protein in the plasma membrane of the fiber cells that make up the bulk of the lens of the mammalian eye. Like other aquaporins, it is a tetramer of identical subunits. The protein's surface is not covered by a set of uniform binding sites for phospholipid molecules. Instead, fatty acyl chains pack tightly against the irregular hydrophobic outer surface of the protein. The

lipids involved in this interaction are referred to as *annular phospholipids* because they form a tight ring (annulus) of lipids around the protein that are not easily exchanged with bulk phospholipids in the bilayer. Some of the fatty acyl chains are straight, in the trans conformation (see Chapter 2), whereas others are kinked in order to interact with bulky hydrophilic side chains on the surface of the protein. Some of the lipid head groups are parallel to the surface of the membrane, as is the case in pure phospholipid bilayers. Others, however, are oriented almost at right angles to the plane of the membrane. Thus there can be specific interactions between phospholipids and membrane-spanning proteins, and the function of many membrane proteins can be affected by the specific types of phospholipids present in the bilayer.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 10-16 Annular phospholipids. Side view of the three- dimensional structure of one subunit of the lens-specific aquaporin 0 homotetramer, crystallized in the presence of the phospholipid dimyristoylphosphatidylcholine, a phospholipid with 14 carbon-saturated fatty acyl (myristic acid) chains. Note the lipid molecules forming a bilayer shell around the protein, which is shown as a surface plot (the lighter background molecule). The lipid molecules are shown in space-filling format; the polar lipid head groups (gray and red) and the lipid fatty acyl chains (the extended black and gray structures) form a bilayer with almost uniform thickness around the protein. Presumably, in the membrane, lipid fatty acyl chains cover the whole of the hydrophobic surface of the protein; only the most ordered of the lipid molecules would be resolved in the crystallographic structure.

[Data from A. Lee, 2005, *Nature* **438**:569–570; and T. Gonen et al., 2005, *Nature* **438**:633–688, PDB ID 2b6o.]

In addition to the predominantly hydrophobic (uncharged) residues that serve to embed integral membrane proteins in the bilayer, many α-helical transmembrane segments contain polar or charged residues. Their amino acid side chains can be used to guide the assembly and stabilization of multimeric membrane proteins. The T-cell receptor for antigen is a case in point: it is composed of four separate dimers, the interactions of which are driven by charge-charge interactions between α helices at the appropriate "depth" in the hydrocarbon core of the lipid bilayer (Figure 10-17). The electrostatic attraction of positive and negative charges on each dimer helps the dimers to find each other. Thus charged residues in otherwise hydrophobic transmembrane segments can help guide assembly of multimeric membrane proteins.

FIGURE 10-17 Charged residues can orchestrate the assembly of multimeric membrane proteins. The T-cell receptor (TCR) for antigen is composed of four separate dimers: an αβ pair directly responsible for antigen recognition and accessory subunits collectively referred to as the *CD3 complex*. These accessory subunits include the γ, δ, ε, and ζ subunits. The ζ subunits form a disulfide-linked homodimer. The γ and δ subunits occur in complex with an ε subunit to generate a γε and a δε pair. The transmembrane segments of the TCR α and β chains each contain positively charged residues (blue). These residues allow recruitment of corresponding δε and γε heterodimers, which carry negative

charges (red) at the appropriate depth in the hydrophobic core of the bilayer. The ζ homodimer docks onto the charges in the TCR α chain (dark green), while the γε and δε subunit pairs find their corresponding partners deeper down in the hydrophobic core on both the TCR α and TCR β chain (light green). Charged residues in otherwise nonpolar transmembrane segments can thus guide assembly of higher order structures.

Multiple β Strands in Porins Form Membrane-Spanning "Barrels"

The **porins** are a class of transmembrane proteins whose structure differs radically from that of other integral membrane proteins based on α-helical transmembrane domains. (Note that the aquaporins discussed above, despite their name, are not porins and contain multiple transmembrane α helices.) Several types of porins are found in the outer membranes of gram-negative bacteria such as *E. coli* (see Figure 1-12a) and in the outer membranes of mitochondria and chloroplasts. The outer membrane protects an intestinal bacterium from harmful agents (e.g., antibiotics, bile salts, and proteases) but permits the uptake and disposal of small hydrophilic molecules, including nutrients and waste products. Different types of porins in the outer membrane of an *E. coli* cell provide channels for the passage of specific types of disaccharides or other small molecules as well as for ions such as phosphate. The

amino acid sequences of porins contain none of the long, continuous hydrophobic segments typical of integral membrane proteins with α-helical membrane-spanning domains. Rather, the entire outer surface of the fully folded porin displays its hydrophobic character to the hydrocarbon core of the lipid bilayer. X-ray crystallography shows that porins are trimers of identical subunits. In each subunit, 16 β strands form a sheet that twists into a barrel-shaped structure with a pore in the center (Figure 10-18). Unlike a typical water-soluble globular protein, a porin has a hydrophilic interior and a hydrophobic exterior; in this sense, porins are inside out. In a porin monomer, the outward-facing side chains on each of the β strands are hydrophobic and form a nonpolar ribbonlike band that encircles the outside of the barrel. This hydrophobic band interacts with the fatty acyl groups of the membrane lipids or with other porin monomers. The side chains facing the inside of a porin monomer are predominantly hydrophilic; they line the pore through which small water-soluble molecules cross the membrane.

FIGURE 10-18 Structural model of one subunit of OmpX, a porin found in the outer membrane of *E. coli*. All porins are trimeric transmembrane proteins. Each subunit

is barrel shaped, with β strands forming the wall and a transmembrane pore in the center. A band of aliphatic (hydrophobic and noncyclic) side chains (yellow) and a border of aromatic (ring-containing) side chains (red) position the protein in the bilayer.

[Data from J. Vogt and G. E. Schulz, 1999, *Structure* **7**:1301, PDB ID 1qj8.]

Recent advances in structural biology, notably the application of cryo-electron microscopy (see Chapter 3) have made it possible to study the structure of membrane proteins, including their transmembrane segments, at near-atomic resolution. Examples include members of the ATP-binding cassette family of transporters (ABC transporters).

Covalently Attached Lipids Anchor Some Proteins to Membranes

In eukaryotic cells, covalently attached lipids anchor some otherwise typically water-soluble proteins to one or the other leaflet of the membrane. In such lipid-anchored proteins, the hydrocarbon chains of the lipid anchor are embedded in the bilayer, but the protein itself does not enter the bilayer. The lipid anchors used to anchor proteins to the cytosolic face are not used for the exoplasmic face, and vice versa.

One group of cytosolic proteins is anchored to the cytosolic face of a membrane by a fatty acyl group (e.g., myristate or palmitate)

covalently attached to an N-terminal glycine residue, a modification called *acylation* (Figure 10-19a). Retention of such proteins at the membrane by the N-terminal acyl anchor may play an important role in a membrane-associated function. For example, v-Src, a mutant form of a cellular tyrosine kinase, induces abnormal cellular growth that can lead to cancer, but does so only when it has a myristylated N-terminus (see Chapter 25).

A second group of cytosolic proteins are anchored to membranes by a hydrocarbon chain attached to a cysteine residue at or near the C-terminus, a modification called *prenylation* (Figure 10-19b). Prenyl anchors are built from 5-carbon isoprene units, which, as detailed in Section 10.3, are also used in the synthesis of cholesterol. In prenylation, a 15-carbon farnesyl or 20-carbon geranylgeranyl group is bound by a thioether bond to the —SH group of a C-terminal cysteine residue of the protein, usually part of a C-terminal Cys-Ala-Ala-X (X = any of a number of amino acids) or CAAX box. Once prenylation has occurred, the C-terminal Ala-Ala-X motif may be removed by proteolysis. In some cases, a second geranylgeranyl group or a fatty acyl palmitate group is linked to a nearby cysteine residue. The additional hydrocarbon anchor is thought to reinforce the attachment of the protein to the membrane. For example, Ras, a GTPase superfamily protein that functions in intracellular signaling (see Chapter 16), is recruited to the cytosolic face of the plasma membrane by such a double anchor. Rab proteins, which also belong to the GTPase superfamily, are similarly bound to the

cytosolic surface of intracellular vesicles by prenyl anchors; these proteins are required for the fusion of vesicles with their target membranes (see Chapter 14). Yet other proteins are palmitoylated on membrane-proximal cysteine residues in the absence of other lipid modifications.

FIGURE 10-19 Anchoring of plasma-membrane proteins to the phospholipid bilayer by covalently linked hydrocarbon groups. (a) Cytosolic proteins such as v-Src are associated with the plasma membrane through a single fatty acyl

chain attached to the N-terminal glycine (Gly) residue of the polypeptide. Myristate (C14) and palmitate (C16) are common acyl anchors. (b) Other cytosolic proteins (e.g., Ras and Rab proteins) are anchored to the membrane by prenylation of one or two cysteine (Cys) residues at or near the C-terminus. The anchors are farnesyl (C15) and geranylgeranyl (C20) groups, both of which are unsaturated. (c) The lipid anchor on the exoplasmic surface of the plasma membrane is glycosylphosphatidylinositol (GPI). The phosphatidylinositol part (red) of this anchor contains two fatty acyl chains that extend into the bilayer. The phosphoethanolamine unit (purple) in the anchor links it to the protein. The two green hexagons represent sugar units, which vary in number, nature, and arrangement in different GPI anchors. The complete structure of a yeast GPI anchor is shown in Figure 13-15.

[Information from H. Sprong et al., 2001, *Nature Rev. Mol. Cell Biol.* **2**:504–513.]

Some cell-surface proteins, and some specialized proteins with distinctive covalently attached polysaccharides called *proteoglycans* (see Chapter 20), are bound to the exoplasmic face of the plasma membrane by a third anchor group, glycosylphosphatidylinositol (GPI) anchors. The exact structures of GPI anchors vary greatly among different cell types, but they always contain phosphatidylinositol, whose two fatty acyl chains extend into the lipid bilayer just like those of typical membrane phospholipids; phosphoethanolamine, which covalently links the anchor to the C-terminus of a protein; and several sugar residues (Figure 10-19c). Therefore, GPI anchors are glycolipids. The GPI anchor is both necessary and sufficient for binding proteins to the membrane. For instance, treatment of cells with phospholipase C, which cleaves the phosphate-glycerol bond in phospholipids and in GPI anchors (see

Figure 10-12), releases GPI-anchored proteins such as Thy-1 and placental alkaline phosphatase (PLAP) from the cell surface.

All Transmembrane Proteins and Glycolipids Are Asymmetrically Oriented in the Bilayer

Every type of transmembrane protein has a specific orientation, known as its *topology*, with respect to the membrane faces. Its cytosolic segments always face the cytosol, and its exoplasmic segments always face the opposite side of the membrane. This asymmetry in protein orientation gives the two membrane faces their different properties. The orientations of different types of transmembrane proteins are established during their synthesis, as we will see in Chapter 13. Membrane proteins have never been observed to flip-flop across a membrane; this would require a transient movement of hydrophilic amino acid residues through the hydrophobic interior of the membrane, which would be energetically unfavorable. Accordingly, the asymmetric topology of a transmembrane protein is maintained throughout the protein's lifetime. As Figure 10-6 shows, membrane proteins retain their asymmetric orientation during membrane budding and fusion events; the same segment always faces the cytosol and the same segment is always exposed to the exoplasmic face. In multipass membrane proteins, the orientation of individual transmembrane

segments can be affected by changes in the membrane's phospholipid composition.

Many transmembrane proteins contain carbohydrate chains covalently linked to serine, threonine, or asparagine side chains of the polypeptide. Such transmembrane **glycoproteins** are always oriented so that all the carbohydrate chains are in the exoplasmic domain (see Figure 10-14 for the example of glycophorin A). Likewise, glycolipids, in which a carbohydrate chain is attached to the glycerol or sphingosine backbone of a membrane lipid, are always located in the exoplasmic leaflet, with the carbohydrate chain protruding from the membrane surface. The biosynthetic basis for the asymmetric glycosylation of proteins is described in Chapters 13 and 14. Both glycoproteins and glycolipids are especially abundant in the plasma membranes of eukaryotic cells and in the membranes of the intracellular compartments that establish the secretory and endocytic pathways; they are absent from the inner mitochondrial membrane, chloroplast lamellae, and several other intracellular membranes. Because the carbohydrate chains of glycoproteins and glycolipids in the plasma membrane extend into the extracellular space, they are available to interact with components of the extracellular matrix as well as with **lectins** (proteins that bind specific sugars), growth factors, and antibodies.

One important consequence of interactions involving membrane glycoproteins and glycolipids is illustrated by the ABO

blood-group antigens. These three structurally related oligosaccharide components of certain glycoproteins and glycolipids are expressed on the surfaces of human red blood cells and many other cell types (Figure 10-20). All humans have the enzymes for synthesizing O antigen. Persons with type A blood also have a glycosyltransferase enzyme that adds an extra modified monosaccharide called N-*acetylgalactosamine* to O antigen to form A antigen. Those with type B blood have a different transferase that adds an extra galactose to O antigen to form B antigen. People with both transferases produce both A and B antigen (AB blood type); those who lack these transferases produce only O antigen (O blood type).

FIGURE 10-20 Human ABO blood-group antigens. These antigens are oligosaccharide chains covalently attached to glycolipids or glycoproteins in the plasma membrane. The terminal oligosaccharide sugars distinguish the three antigens. The presence or absence of the glycosyltransferases that add galactose (Gal) or *N*-acetylgalactosamine (GalNAc) to O antigen determine a person's blood type.

People whose erythrocytes lack the A antigen, the B antigen, or both on their surface normally have antibodies against the missing antigen(s) in their serum. Thus if a type A or O person receives a transfusion of type B blood, antibodies against the B antigen will bind to the introduced red cells and trigger their destruction. To

prevent such harmful reactions, blood-group typing and appropriate matching of blood donors and recipients are required in all transfusions (Table 10-2). ■

TABLE 10-2 • ABO Blood Groups

Blood Group	Antigens on RBCs[i]	Serum Antibodies	Can Receive Blood Types
A	A	Anti-B	A and O
B	B	Anti-A	B and O
AB	A and B	None	All
O	O	Anti-A and anti-B	O

[i]See Figure 10-20 for antigen structures.

Lipid-Binding Motifs Help Target Peripheral Proteins to the Membrane

Many water-soluble enzymes whose substrates are phospholipids must bind to membrane surfaces. Phospholipases, for example, hydrolyze various bonds in the head groups of phospholipids (see Figure 10-12) and thereby play a variety of roles in cells — helping to degrade damaged or aged cellular membranes, generating precursors to signaling molecules, and even serving as the active

components in many snake venoms. Many peripheral proteins, including phospholipases, initially bind to the polar head groups of membrane phospholipids to carry out their catalytic functions. The mechanism of action of phospholipase A_2 illustrates how such enzymes can reversibly interact with membranes and catalyze reactions at the interface of an aqueous solution and a lipid surface. When this enzyme is in aqueous solution, its Ca^{2+}-containing active site is buried in a channel lined with hydrophobic amino acids. The enzyme binds with greatest affinity to bilayers composed of negatively charged phospholipids (e.g., phosphatidylserine). This observation suggests that the rim of positively charged lysine and arginine residues around the entrance to the catalytic channel is particularly important in binding (Figure 10-21a) and constitutes a lipid binding motif. Binding induces a conformational change in phospholipase A_2 that strengthens its binding to the phospholipid heads and opens the hydrophobic channel. As a phospholipid molecule moves from the bilayer into the channel, the enzyme-bound Ca^{2+} binds to the phosphate in the head group, thereby positioning the ester bond to be cleaved in the catalytic site (Figure 10-21b), releasing the acyl chain.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 10-21 Lipid-binding surface and mechanism of action of phospholipase A_2. (a) A structural model of the enzyme, showing the surface that interacts with a membrane. This lipid-binding surface contains a rim of positively charged arginine and lysine residues (blue), surrounding the cavity of the catalytic active site, in which a substrate lipid (red ball-and-stick structure) is bound. (b) Diagram of catalysis by phospholipase A_2. When docked on a lipid membrane, positively charged residues of the binding site bind to negatively charged polar groups at the membrane surface. This binding triggers a small conformational change, opening a channel lined with hydrophobic amino acids that leads from the bilayer to the catalytic site. As a phospholipid moves into the channel, an enzyme-bound Ca^{2+} ion (green) binds to the head group, positioning the ester bond to be cleaved (red) next to the catalytic site. See D.

Proteins Can Be Removed from Membranes by Detergents or High-Salt Solutions

Membrane proteins are often difficult to purify and study, mostly because of their tight association with membrane lipids and other membrane proteins. *Detergents,* which are amphipathic molecules that disrupt membranes by intercalating into phospholipid bilayers, can be used to solubilize lipids and many membrane proteins. The hydrophobic part of a detergent molecule is attracted to the phospholipid hydrocarbons and mingles with them readily; the hydrophilic part is strongly attracted to water. Some detergents, such as bile salts, are natural products, but most are synthetic molecules developed for cleaning and for dispersing mixtures of oil and water in the food industry (e.g., to keep salad dressings from separating). Ionic detergents, such as sodium deoxycholate (a bile salt) and sodium dodecylsulfate (SDS), contain a charged group; non-ionic detergents, such as Triton X-100 and octylglucoside, lack a charged group (Figure 10-22). At very low concentrations, detergents dissolve in pure water as isolated molecules. As the concentration increases, the molecules begin to form micelles — small spherical

aggregates in which the hydrophilic parts of the molecules face outward and the hydrophobic parts cluster in the center (see Figure 10-3c). The *critical micelle concentration (CMC)* at which micelles form is characteristic of each detergent and is a function of the structures of its hydrophobic and hydrophilic parts.

FIGURE 10-22 Structures of four common detergents. The hydrophobic part of each molecule is shown in yellow; the hydrophilic part, in blue. The bile salt sodium deoxycholate is a natural product; the others are synthetic. Although ionic detergents commonly cause denaturation of proteins, non-ionic detergents do not and are thus useful in solubilizing integral membrane proteins.

Ionic and non-ionic detergents interact differently with proteins and have different uses in the lab. Ionic detergents bind to the exposed hydrophobic regions of membrane proteins as well as to the hydrophobic cores of water-soluble proteins. Because of their charge, these detergents can disrupt ionic and hydrogen bonds. At

high concentrations, sodium dodecylsulfate, for example, completely denatures proteins by binding to every side chain, a property that is exploited in SDS gel electrophoresis (see Figure 3-41). Non-ionic detergents generally do not denature proteins and are thus useful in extracting proteins in their folded and active form from membranes before the proteins are purified. Protein-protein interactions, especially the weaker ones, can be sensitive to both ionic and non-ionic detergents.

At high concentrations (above the CMC), non-ionic detergents solubilize biological membranes by forming mixed micelles of detergent, phospholipids, and integral membrane proteins — bulky hydrophobic structures that do not dissolve in water (Figure 10-23, *top*). At low concentrations (below the CMC), these detergents bind to the hydrophobic regions of most integral membrane proteins, but without forming micelles, allowing the proteins to remain soluble (Figure 10-23, *bottom*). Creating such an aqueous solution of integral membrane proteins is a necessary first step in protein purification.

FIGURE 10-23 Solubilization of integral membrane proteins by non-ionic detergents. At a concentration higher than its critical micelle concentration (CMC), a detergent solubilizes lipids and integral membrane proteins, forming mixed micelles containing detergent, protein, and lipid molecules. At concentrations below the CMC, non-ionic detergents (e.g., octylglucoside, Triton X-100) can dissolve membrane proteins without forming micelles by coating the membrane-spanning regions.

Treatment of cultured cells with a buffered salt solution containing a non-ionic detergent such as Triton X-100 extracts water-soluble proteins as well as integral membrane proteins from cellular membranes. As noted earlier, the exoplasmic and cytosolic domains of integral membrane proteins are generally hydrophilic and soluble in water. The membrane-spanning domains, however, are rich in hydrophobic and uncharged residues (see Figure 10-14). When separated from membranes, these exposed hydrophobic segments tend to interact with one another, causing the protein molecules to

aggregate and precipitate from aqueous solutions. The hydrophobic parts of non-ionic detergent molecules preferentially bind to the hydrophobic segments of transmembrane proteins, preventing protein aggregation and allowing the proteins to remain in aqueous solution. Detergent-solubilized transmembrane proteins can then be purified by affinity chromatography and other techniques used in purifying water-soluble proteins (see Chapter 3).

As discussed previously, most peripheral membrane proteins are bound to specific transmembrane proteins or membrane phospholipids by ionic or other weak noncovalent interactions. Generally peripheral proteins can be removed from the membrane by solutions of high ionic strength (high salt concentrations), which disrupt ionic bonds, or by chemicals that bind divalent cations such as Mg^{2+}. Unlike integral membrane proteins, most peripheral proteins are soluble in water and do not need to be solubilized by non-ionic detergents.

The localization of membrane proteins to the phospholipid bilayer is not necessarily permanent. Phosphatidylinositide-specific phospholipase C hydrolyzes the membrane anchor of proteins attached to the membrane via this hydrophobic tail. Similarly, proteases can “shave off” the extracellular portions of single-pass membrane proteins. This can be done experimentally, for example, by exposing cells or membranes derived from them to a protease such as papain, and often allows recovery of the released extracellular portion for structural and functional studies. These

and similar methods are commonly used to detach cultured mammalian cells from the solid supports on which they are often grown or to detach cells from tissues to generate single cell suspensions. However, many single-pass membrane proteins are natural substrates for *sheddases*: members of the metalloprotease family of proteases that are discussed in Chapter 16. The extracellular domains released in this fashion may be found in the circulation and exert biological functions distinct from their membrane-anchored equivalents.

KEY CONCEPTS OF SECTION 10.2

Membrane Proteins: Structure and Basic Functions

- Biological membranes usually contain integral (transmembrane) proteins as well as lipid-anchored proteins and peripheral membrane proteins, which do not enter the hydrophobic core of the bilayer (see Figure 10-1).
- Most integral membrane proteins contain one or more membrane-spanning hydrophobic α helices, which are bracketed by hydrophilic domains that extend into the aqueous environment surrounding the cytosolic and exoplasmic faces of the membrane (see Figures 10-14, 10-15, and 10-17).
- Fatty acyl side chains as well as the polar head groups of membrane lipids pack tightly and irregularly around the hydrophobic segments of integral membrane proteins (see Figure 10-16).
- The porins, unlike other integral membrane proteins, contain membrane-spanning β sheets that form a barrel-like channel through the bilayer (see Figure 10-18).
- Lipids attached to certain amino acids anchor some proteins to one or the other membrane leaflet (see Figure 10-19).
- All transmembrane proteins and glycolipids are asymmetrically oriented in the bilayer. Invariably, carbohydrate chains are present only on the exoplasmic surface of a glycoprotein or glycolipid.
- Many water-soluble enzymes (e.g., phospholipases) whose substrates are phospholipids must bind to the membrane surface to carry out their function. Such

binding is often due to the attraction between positive charges on lysine and arginine residues in the protein and negative charges on phospholipid head groups in the bilayer.

- Transmembrane proteins can be selectively extracted from membranes with the use of non-ionic detergents.

10.3 Phospholipids, Sphingolipids, and Cholesterol: Synthesis and Intracellular Movement

In this section, we consider some of the special challenges that a cell faces in synthesizing and transporting lipids, which are poorly soluble in the aqueous interior of a cell. The focus will be the biosynthesis and movement of the major lipids found in cellular membranes — phospholipids, sphingolipids, and cholesterol — and their precursors. In lipid biosynthesis, water-soluble precursors are assembled into membrane-associated intermediates that are then converted into membrane lipid products. The movement of these lipids, especially membrane components, between different organelles is critical for maintaining the proper composition and properties of membranes and overall cell structure.

A fundamental principle of membrane biosynthesis is that cells synthesize new membranes only by the expansion of existing membranes. [The one exception may be autophagy, in which new membrane is formed first through the formation of an autophagic crescent, the construction of which involves modification of phosphatidylethanolamine with the ubiquitin-like modifier Atg8 (see Figure 14-34).] Although some early steps in the synthesis of membrane lipids take place in the cytosol, the final steps are catalyzed by enzymes bound to preexisting cellular membranes, and

the products are incorporated into the membranes as they are generated. Evidence for this process is seen when cells are briefly exposed to radioactively labeled precursors (e.g., phosphates or fatty acids): all the phospholipids and sphingolipids incorporating these labeled precursors are associated with intracellular membranes; as expected from the hydrophobicity of the fatty acyl chains, none are found free in the cytosol.

After they are formed, membrane lipids must be distributed appropriately both between the leaflets of a given membrane and among the independent membranes of different organelles in eukaryotic cells, as well as the plasma membrane. Here we consider how this precise lipid distribution is accomplished; in Chapters 13 and 14, we discuss how membrane proteins are inserted into cellular membranes and trafficked to their appropriate location within the cell.

Fatty Acids Are Assembled from Two-Carbon Building Blocks by Several Important Enzymes

Fatty acids (see Chapter 2) play a number of important roles in cells. In addition to being a cellular fuel source (see the discussion of aerobic oxidation in Chapter 12), fatty acids are key components of both the phospholipids and the sphingolipids that make up cellular

membranes; they also anchor some proteins to cellular membranes (see Figure 10-19). Thus the regulation of fatty acid synthesis plays a key role in the regulation of membrane synthesis as a whole. The major fatty acids in phospholipids contain 14, 16, 18, or 20 carbon atoms and include both saturated and unsaturated chains. The fatty acyl chains found on sphingolipids can be longer than those in the phosphoglycerides, containing up to 26 carbon atoms, and may bear other chemical modifications (e.g., hydroxylation) as well.

Fatty acids are synthesized from the two-carbon building block acetate (CH_3COO^-). In cells, both acetate and the intermediates in fatty acid biosynthesis are esterified to a large water-soluble molecule called *coenzyme A (CoA)*, as exemplified by the structure of **acetyl CoA** shown here.

Acetyl CoA is an important intermediate in the metabolism of glucose, fatty acids, and many amino acids, as detailed in Chapter 12. It also contributes acetyl groups in many biosynthetic pathways. **Saturated** fatty acids (with no carbon-carbon double bonds) containing 14 or 16 carbon atoms are made from acetyl CoA by two enzymes, acetyl-CoA carboxylase *and* fatty acid synthase. In animal cells, these enzymes are found in the cytosol; in plants, they are

found in chloroplasts. Palmitoyl CoA (a 16-carbon fatty acyl group linked to CoA) can be elongated to 18–24 carbons by the sequential addition of two-carbon units in the endoplasmic reticulum (ER) or sometimes in the mitochondrion. Desaturase enzymes, also located in the ER, introduce double bonds at specific positions in some fatty acids, yielding **unsaturated** fatty acids. Oleyl CoA (oleate linked to CoA; see Table 2-4), for example, is formed by removal of two H atoms from stearyl CoA. In contrast to free fatty acids, fatty acyl CoA derivatives are soluble in aqueous solutions because of the hydrophilicity of the CoA segment.

Small Cytosolic Proteins Facilitate Movement of Fatty Acids

In order to be transported through the cell cytosol, free, or unesterified, fatty acids (those unlinked to CoA) are commonly bound by *fatty acid–binding proteins (FABPs)*, which belong to a group of small cytosolic proteins that act as chaperones to facilitate the intracellular movement of many lipids. These proteins contain a hydrophobic pocket lined by β sheets (Figure 10-24). A long-chain fatty acid can fit into this pocket and interact noncovalently with the surrounding protein.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 10-24 Binding of a fatty acid to the hydrophobic pocket of a fatty acid–binding protein (FABP). The crystal structure of adipocyte FABP (ribbon diagram) shows that the hydrophobic binding pocket is generated from two β sheets that are nearly at right angles to each other, forming a clam shell–like structure. A fatty acid (carbons yellow; oxygens red) interacts noncovalently with hydrophobic amino acid residues within this pocket.

[Data from Z. Xu, D. A. Bernlohr, and L. J. Banaszak, 1993, *J. Biol. Chem.* **268**:7874, PDB ID 1lid.]

The expression of cellular FABPs is regulated coordinately with cellular requirements for the uptake and release of fatty acids. Thus FABP levels are high in active muscles that are using fatty acids for generation of ATP, and in adipocytes (fat-storing cells) when they

are either taking up fatty acids to be stored as triglycerides or releasing fatty acids for use by other cells. The importance of FABPs in fatty acid metabolism is highlighted by the observations that they can compose as much as 5 percent of all cytosolic proteins in the liver and that genetic inactivation of cardiac muscle FABP converts the heart from a muscle that primarily burns fatty acids for energy into one that primarily burns glucose.

Fatty Acids Are Incorporated into Phospholipids Primarily on the ER Membrane

Fatty acids are not directly incorporated into phospholipids; rather, in eukaryotic cells, they are first converted into CoA esters. The subsequent synthesis of phospholipids such as the phosphoglycerides is carried out by enzymes associated with the cytosolic face of the ER membrane, usually the smooth ER, in animal cells; through a series of steps, fatty acyl CoAs, glycerol 3-phosphate, and polar head group precursors are linked together and then inserted into the ER membrane (Figure 10-25). The fact that the enzymes involved in this process are located on the cytosolic side of the membrane means that there is an inherent asymmetry in membrane biogenesis: new membranes are initially synthesized only on one leaflet — a fact with important consequences for the asymmetric distribution of lipids in membrane leaflets. Once

synthesized on the ER, phospholipids are transported to other organelles and to the plasma membrane. Mitochondria synthesize some of their own membrane lipids and import others.

FIGURE 10-25 Phospholipid synthesis in the ER membrane. Because phospholipids are amphipathic molecules, the last steps of their multistep synthesis take place at the interface between a membrane and the cytosol and are catalyzed by membrane-associated enzymes. Step 1: Two fatty acids from fatty acyl CoA are esterified to the phosphorylated glycerol backbone, forming phosphatidic acid, whose two long hydrocarbon chains anchor the molecule to the membrane. Step 2: A phosphatase converts phosphatidic acid into diacylglycerol. Step 3: A polar head group (e.g., phosphorylcholine) is transferred from cytosine diphosphocholine (CDP-choline) to the exposed hydroxyl group. Step 4: Flippase proteins catalyze the movement of phospholipids from the cytosolic leaflet in which they are initially formed to the exoplasmic leaflet.

Sphingolipids are also synthesized indirectly from multiple precursors. Sphingosine, the building block of these lipids, is made in the ER, beginning with the coupling of a palmitoyl group from palmitoyl CoA to serine; the subsequent addition of a second fatty

acyl group to form *N*-acyl sphingosine (ceramide) also takes place in the ER. Later, in the Golgi, a polar head group is added to ceramide, yielding *sphingomyelin*, whose head group is phosphorylcholine, and various *glycosphingolipids*, in which the head group may be a monosaccharide or a more complex oligosaccharide (see Figure 10-8b). Some sphingolipid synthesis can also take place in mitochondria. In addition to serving as the backbone for sphingolipids, ceramide and its metabolic products are important signaling molecules that can influence cell growth, proliferation, endocytosis, resistance to stress, and programmed cell death (apoptosis).

After their synthesis is completed in the Golgi, sphingolipids are transported to other cellular compartments through vesicle-mediated mechanisms similar to those for the transport of proteins, discussed in Chapter 14. Any type of vesicular transport results in movement not only of the protein payload but also of the lipids that compose the vesicular membrane. Phospholipids such as phosphoglycerides, as well as cholesterol, can move between organelles by additional mechanisms, described below.

Flippases Move Phospholipids from One Membrane Leaflet to the Opposite Leaflet

Even though phospholipids are initially incorporated into the cytosolic leaflet of the ER membrane, various phospholipids are asymmetrically distributed in the two leaflets of the ER membrane and of other cellular membranes. As noted above, phospholipids do not readily flip-flop from one leaflet to the other. For the ER membrane to expand by growth of both leaflets and to have asymmetrically distributed phospholipids, its phospholipid components must be able to move from one leaflet to the other. Although the mechanisms employed to generate and maintain membrane phospholipid asymmetry are not well understood, it is clear that flippases play a key role. As will be described in Chapter 11, these integral membrane proteins use the energy of ATP hydrolysis to facilitate the movement of phospholipid molecules from one leaflet to the other. When cells die, this lipid asymmetry is lost and results in increased surface exposure of those phospholipids mostly confined to the cytoplasmic leaflet, such as phosphatidylserine.

Cholesterol Is Synthesized by Enzymes in the Cytosol and ER Membrane

Next we focus on cholesterol, the principal sterol in animal cells. Cholesterol is synthesized mainly in the liver. The first steps of cholesterol synthesis (Figure 10-26) — conversion of three acetyl groups linked to CoA (acetyl CoA) forming the six-carbon molecule

β-hydroxy-β-methylglutaryl linked to CoA (HMG-CoA) — take place in the cytosol. The conversion of HMG-CoA into mevalonate, the key rate-controlling step in cholesterol biosynthesis, is catalyzed by *HMG-CoA reductase*, an ER integral membrane protein, even though both its substrate and its product are water soluble. The water-soluble catalytic domain of HMG-CoA reductase extends into the cytosol, but its eight transmembrane α helices firmly embed the enzyme in the ER membrane. Five of the transmembrane α helices compose the so-called *sterol-sensing domain* and regulate enzyme stability. When levels of cholesterol in the ER membrane are high, binding of cholesterol to this domain causes the enzyme to bind to two other integral ER membrane proteins, Insig-1 and Insig-2. This binding, in turn, induces ubiquitylation (see Figure 3-32) of HMG-CoA reductase and its degradation by the proteasome pathway, reducing the production of mevalonate, the key intermediate in cholesterol biosynthesis.

FIGURE 10-26 Cholesterol biosynthetic pathway. The regulated rate-controlling step in cholesterol biosynthesis is the conversion of β-hydroxy-β-methylglutaryl CoA (HMG-CoA) into mevalonate by HMG-CoA reductase, an ER-membrane protein. Mevalonate is then converted into isopentenyl pyrophosphate (IPP), which has the basic five-carbon isoprenoid structure. IPP can be converted into cholesterol and many other lipids, often through the polyisoprenoid intermediates shown. Some of the numerous compounds derived from isoprenoid intermediates and cholesterol itself are indicated.

Atherosclerosis, frequently called *cholesterol-dependent clogging of the arteries*, is characterized by the progressive deposition of cholesterol and other lipids, cells, and extracellular matrix material in the inner layer of the wall of an artery. The resulting distortion of the artery's wall can lead, either alone or in combination with a

blood clot, to major blockage of blood flow. Atherosclerosis accounts for 75 percent of deaths due to cardiovascular disease in the United States.

Perhaps the most successful anti-atherosclerosis medications are the *statins*. These drugs bind to HMG-CoA reductase and directly inhibit its activity, thereby lowering cholesterol biosynthesis. As a consequence, the concentration of low-density lipoproteins (see Figure 14-27) — the small, membrane-enveloped particles containing cholesterol esterified to fatty acids that often and rightly are called "bad cholesterol" — drops in the blood, reducing the formation of atherosclerotic plaques. ■

Mevalonate, the six-carbon product formed by HMG-CoA reductase, is converted in several steps into the five- carbon isoprenoid compound isopentenyl pyrophosphate (IPP) and its stereoisomer, dimethylallyl pyrophosphate (DMPP) (see Figure 10-26). These reactions are catalyzed by cytosolic enzymes, as are the subsequent reactions in the cholesterol synthesis pathway, in which six IPP units condense to yield squalene, a branched-chain 30-carbon intermediate. Enzymes bound to the ER membrane catalyze the multiple reactions that convert squalene into cholesterol in mammals or into related sterols in other species. One of the intermediates in this pathway, farnesyl pyrophosphate, is the precursor of the prenyl lipid that anchors Ras and related proteins to

the cytosolic surface of the plasma membrane (see Figure 10-19) as well as other important biomolecules (see Figure 10-26).

Cholesterol and Phospholipids Are Transported Between Organelles by Several Mechanisms

As already noted, the final steps in the synthesis of cholesterol and phospholipids take place primarily in the ER. Thus the plasma membrane and the membranes bounding other organelles must obtain these lipids by means of one or more intracellular transport processes. Membrane lipids can and do accompany both soluble and membrane proteins along the secretory pathway described in Chapter 14: membrane vesicles bud from the ER and fuse with membranes in the Golgi complex, and other membrane vesicles bud from the Golgi complex and fuse with the plasma membrane (Figure 10-27a). However, evidence suggests that there is substantial inter-organelle movement of cholesterol and phospholipids through other mechanisms. For example, chemical inhibitors of the classic secretory pathway and mutations that impede vesicular traffic along this pathway do not prevent cholesterol or phospholipid transport between membranes.

FIGURE 10-27 Proposed mechanisms of transport of cholesterol and phospholipids between membranes. In mechanism (a), vesicles transfer lipids between membranes. In mechanism (b), lipid transfer is a consequence of direct contact between membranes that is mediated by membrane-embedded proteins. In mechanism (c), transfer is mediated by small, soluble lipid-transfer proteins.

[Information from F. R. Maxfield and D. Wustner, 2002, *J. Clin. Invest.* **110**:891.]

A second proposed mechanism of lipid movement entails direct protein-mediated contact of ER or ER-derived membranes with the membranes of other organelles (Figure 10-27b). In a third proposed mechanism, small lipid-transfer proteins facilitate the exchange of phospholipids or cholesterol between different membranes (Figure 10-27c). Although such lipid-transfer proteins have been identified in assays in vitro, their role in the intracellular movements of most phospholipids is not well defined. For instance, mice with a knockout mutation in the gene encoding the phosphatidylcholine-transfer protein appear to be normal in most respects, indicating that this protein is not essential for cellular phospholipid metabolism.

As noted earlier, the lipid compositions of different organelle membranes vary considerably (see Table 10-1). Some of these differences are due to different sites of synthesis. For example, a phospholipid called *cardiolipin*, which is localized to the mitochondrial membrane, is made only in mitochondria, and little of it is transferred to other organelles. Differential transport of lipids also plays a role in determining the lipid compositions of different cellular membranes. For instance, even though cholesterol is made in the ER, the cholesterol concentration (cholesterol-to-phospholipid molar ratio) is 1.5–13-fold higher in the plasma membrane than in other organelles (ER, Golgi, mitochondrion, lysosome). Although the mechanisms responsible for establishing and maintaining these differences are not well understood, we have seen that the distinctive lipid composition of each membrane has a major influence on its physical and biological properties.

KEY CONCEPTS OF SECTION 10.3

Phospholipids, Sphingolipids, and Cholesterol: Synthesis and Intracellular Movement

- Saturated and unsaturated fatty acids of various chain lengths are components of phospholipids and sphingolipids.
- Fatty acids are synthesized from acetyl CoA by water-soluble enzymes and modified by elongation and desaturation in the endoplasmic reticulum (ER).
- Free fatty acids are transported within cells by fatty acid–binding proteins (FABPs).
- Fatty acids are incorporated into phospholipids through a multistep process. The final steps in the synthesis of phosphoglycerides and sphingolipids are catalyzed by membrane-associated enzymes primarily on the cytosolic face of the ER (see Figure 10-25).

- Each type of newly synthesized lipid is incorporated into the preexisting membranes on which it is made; thus membranes are themselves the platform for the synthesis of new membrane material.
- Most membrane phospholipids are preferentially distributed in either the exoplasmic or the cytosolic leaflet. This asymmetry results in part from the action of flippases, which flip phospholipids from one leaflet to the other.
- The initial steps in cholesterol biosynthesis take place in the cytosol, whereas the last steps are catalyzed by enzymes associated with the ER membrane.
- The rate-controlling step in cholesterol biosynthesis is catalyzed by HMG-CoA reductase, whose transmembrane segments are embedded in the ER membrane and contain a sterol-sensing domain.
- Considerable evidence indicates that vesicular transport, direct protein-mediated contacts between different membranes, soluble lipid-transfer proteins, or all three may account for some inter-organelle transport of cholesterol and phospholipids (see Figure 10-27).

Review the Concepts

1. When viewed by electron microscopy, the lipid bilayer is often described as looking like a railroad track. Explain how the structure of the bilayer creates this image.
2. Explain the following statement: The structure of all biomembranes depends on the chemical properties of phospholipids, whereas the function of each specific

biomembrane depends on the specific proteins associated with that membrane.

3. Biomembranes contain many different types of lipid molecules. What are the three main types of lipid molecules found in biomembranes? How are the three types similar, and how are they different?
4. Lipid bilayers are said to behave like two-dimensional fluids. What does this mean? What drives the movement of lipid molecules and proteins within the bilayer? How can such movement be measured? What factors affect the degree of membrane fluidity?
5. Why are water-soluble substances unable to freely cross the lipid bilayer of the plasma membrane? How does the cell overcome this permeability barrier?
6. Name the three groups into which membrane-associated proteins may be classified. Explain the mechanism by which each group associates with a biomembrane.
7. Identify the following membrane-associated proteins based on their structure: (a) tetramers of identical subunits, each with six membrane-spanning α helices; (b) trimers of identical subunits, each with 16 β sheets forming a barrel-like structure.
8. Proteins may be bound to the exoplasmic or cytosolic face of the plasma membrane by covalently attached lipids. What are the three types of lipid anchors responsible for tethering proteins to the plasma-membrane bilayer? Which type is used by cell-surface proteins that face the external medium? By glycosylated proteoglycans?

9. Although both faces of a biomembrane are composed of the same general types of macromolecules, principally lipids and proteins, the two faces of the bilayer are not identical. What accounts for the asymmetry between the two faces?
10. What are detergents? How do ionic and non-ionic detergents differ in their ability to disrupt biomembrane structure?
11. What is the likely identity of these membrane-associated proteins: (a) a protein that is released from a membrane treated with a high-salt solution, which causes disruption of ionic linkages; (b) a protein that is not released from the membrane upon its exposure to a high-salt solution alone, but is released when the membrane is incubated with an enzyme that cleaves phosphate-glycerol bonds and covalent linkages are disrupted; (c) a protein that is not released from the membrane upon exposure to a high-salt solution, but is released after the addition of the detergent sodium dodecylsulfate (SDS). Will the activity of the protein released in part (c) be preserved following its release?
12. Following the production of membrane extracts using the non-ionic detergent Triton X-100, you analyze the membrane lysates via mass spectrometry and note a high content of cholesterol and sphingolipids. Furthermore, biochemical analysis of the lysates shows potential kinase activity. What have you probably isolated?
13. Phospholipid biosynthesis at the interface between the endoplasmic reticulum (ER) and the cytosol presents a

number of challenges that must be solved by the cell. Explain how each of the following is handled.

a. The substrates for phospholipid biosynthesis are all water soluble, yet the end products are not.
b. The immediate site of incorporation of all newly synthesized phospholipids is the cytosolic leaflet of the ER membrane, yet phospholipids must be incorporated into both leaflets.
c. Many membrane systems in the cell, such as the plasma membrane, are unable to synthesize their own phospholipids, yet these membranes must also expand if the cell is to grow and divide.

14. What are the common fatty acid chains in phosphoglycerides, and why do these fatty acid chains differ in their number of carbon atoms by multiples of 2?
15. Fatty acids must associate with lipid chaperones in order to move within the cell. Why are these chaperones needed, and what is the name given to a group of proteins that are responsible for this intracellular trafficking of fatty acids? What is the key distinguishing feature of these proteins that allows fatty acids to move within the cell?
16. What is the key enzyme in the highly regulated process of cholesterol biosynthesis? This enzyme is subject to feedback inhibition. What is feedback inhibition? How does this enzyme sense cholesterol levels in a cell?
17. Phospholipids and cholesterol must be transported from their site of synthesis to various membrane systems within cells. One way of doing this is through vesicular transport,

as is the case for many proteins in the classic secretory pathway (see Chapter 14). However, phospholipid and cholesterol membrane-to-membrane transport in cells does not occur solely by vesicular transport. What is the evidence for this? What appear to be the major mechanisms for phospholipid and cholesterol transport?

18. Explain the mechanism by which statins lower “bad” cholesterol.

CHAPTER 11

Transmembrane Transport of Ions and Small Molecules

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

Transmembrane, side view of the human glucose transporter GLUT1. Like other glucose transporters, GLUT1 transports glucose across the cell's plasma membrane by alternating between an outward-facing and an inward-facing state. In the outward-facing state, a molecule of glucose binds to GLUT1. Glucose binding changes the conformation of the transporter such that it is now open to the inside of the cell, releasing glucose into the cytoplasm.

[Data from D. Deng et al., 2014 *Nature* **510**:121–125, PDB ID 4PYP.]

OUTLINE

11.1 Overview of Transmembrane Transport
11.2 Facilitated Transport of Glucose and Water
11.3 ATP-Powered Pumps and the Intracellular Ionic Environment
11.4 Nongated Ion Channels and the Resting Membrane Potential
11.5 Cotransport by Symporters and Antiporters
11.6 Transcellular Transport

In all cells, the plasma membrane forms the barrier that separates the cytoplasm from the exterior environment, thus defining a cell's physical and chemical boundaries. By preventing the unimpeded movement of molecules and ions into and out of the cell, the plasma membrane maintains essential differences between the composition of the fluid inside the cell (the cytosol) and the fluid outside the cell (the extracellular fluid). For example, the concentration of sodium ion (Na^+) in the cytosol of animal cells is about 15 mM, while the concentration of sodium chloride (NaCl) in extracellular fluids, including blood, of animals is tenfold higher, about 150 mM. Conversely, the potassium ion (K^+) concentration is tenfold higher in the cytosol of animal cells than in the extracellular fluid. As we describe in Section 11.4, these differences in the distribution of ions across the plasma membrane are critical to establishing and maintaining the membrane potential of the cell.

Organelle membranes, which separate the cytosol from the interior of the organelle, also form permeability barriers. For example, the proton concentration in the lysosome interior, pH 5, is about a hundredfold greater than that in the cytosol, and many specific metabolites accumulate at higher concentrations in the interior of

other organelles, such as the endoplasmic reticulum or the Golgi complex, than in the cytosol.

All cellular membranes, both plasma membranes and organelle membranes, consist of a bilayer of phospholipids in which other lipids and specific types of proteins are embedded. It is this combination of lipids and proteins that gives cellular membranes their distinctive permeability qualities. If cellular membranes were pure phospholipid bilayers (see Figure 9-5), they would be excellent chemical barriers, impermeable to virtually all ions, amino acids, sugars, and other water-soluble molecules. In fact, only a few gases and small, uncharged, water-soluble molecules can readily diffuse across a pure phospholipid bilayer (Figure 11-1). Cellular membranes must serve not only as barriers but also as conduits, selectively transporting molecules and ions from one side of the membrane to the other. Energy-rich glucose, for example, must be imported into the cell, and wastes must be shipped out.

FIGURE 11-1 Relative permeability of a pure phospholipid bilayer to various molecules and ions. A pure phospholipid bilayer is permeable to many gases and to small, uncharged, water-soluble (polar) molecules. It is slightly permeable to water, and essentially impermeable to ions and to large polar molecules.

Movement of virtually all small molecules and ions across cellular membranes is mediated by **membrane transport proteins** — integral membrane proteins with multiple transmembrane domains embedded in cellular membranes. These membrane-spanning proteins act as shuttles, channels, or pumps for transporting

molecules and ions through a membrane's hydrophobic interior. In some cases, these proteins transport molecules or ions from a higher to a lower concentration, a thermodynamically favored process powered by an increase in entropy. Examples include the transport of water or glucose from the blood into most body cells. In other cases, a transport protein pumps molecules or ions from a lower to a higher concentration, a thermodynamically unfavorable process that can occur only when an external source of energy is available to push the molecules *uphill* against a concentration gradient. An example of such a process is the movement of protons into lysosomes to generate a low pH in the lumen. Often the required energy is provided by mechanistic coupling of the energy-releasing hydrolysis of ATP with the movement of a molecule or ion across the membrane. Other transport proteins couple the movement of one molecule or ion against its concentration gradient with the movement of another down its gradient, using the energy released by the *downhill* movement of one molecule or ion to drive the uphill movement of another. Proper functioning of any cell relies on a precise balance between the import and export of various molecules and ions.

We begin our discussion of membrane transport proteins by reviewing some of the general principles of transport across membranes and distinguishing among three major classes of such proteins. In subsequent sections, we describe the structure and operation of specific examples of each class and show how members

of families of homologous transport proteins have different properties that enable different cell types to function appropriately. We also explain how specific combinations of transport proteins in both the plasma membrane and organelle membranes enable cells to carry out essential physiological processes, including the maintenance of cytosolic pH, the direction of the flow of water in both plant and animal cells, and the transport of sugar and amino acids into cells.

The identification of many disease-causing mutations in membrane transporters underscores the importance of this class of molecules to human health. Mutations in these proteins cause a range of diseases, including cystic fibrosis and long QT syndrome (a potentially fatal form of cardiac arrhythmia) as well as specific forms of epilepsy, migraine, ataxia, polycystic kidney disease, and congenital hearing loss. As highlighted throughout this chapter, channels, transporters, and pumps are the targets of a growing number of therapeutic drugs. Recent advances in powerful new imaging technologies, such as cryo-electron microscopy (cryo-EM, see Figure 4-34), have given rise to an explosion of discoveries about the structure and function of many of these membrane proteins. These discoveries in turn promise to lead to the development of new, lifesaving therapies. Our increased understanding of channel structure and function has also led to the development of heterologously expressed channels that can be activated by light (optogenetic) or drugs (chemogenetic). These have become powerful

tools to control biochemical processes (described in Chapter 4) and neural circuits (described in Chapter 23).

Note that in this chapter we cover only transport of small molecules and ions; transport of larger molecules, such as proteins and oligosaccharides, is covered in Chapters 13 and 14.

11.1 Overview of Transmembrane Transport

In this section, we briefly describe the factors that influence the permeability of lipid membranes to molecules, then briefly describe the three major classes of membrane transport proteins that allow molecules and ions to cross them. Different kinds of membrane-embedded proteins accomplish the task of moving molecules and ions in different ways.

Only Gases and Small Uncharged Molecules Cross Membranes by Simple Diffusion

With its dense hydrophobic core, a phospholipid bilayer is largely impermeable to water-soluble molecules and ions. Only gases, such as O_2 and CO_2, and small uncharged polar molecules, such as urea and ethanol, can readily move across an artificial membrane composed of pure phospholipid or of phospholipid and cholesterol (see Figure 11-1). Such molecules can also diffuse across cellular membranes without the aid of transport proteins. No metabolic energy is expended during simple diffusion because movement is from a high to a low concentration of the molecule, down its chemical concentration gradient. Such movements are spontaneous

because they have a positive ΔS value (increase in entropy) and thus a negative ΔG (decrease in free energy). The diffusion rate of any substance across a pure phospholipid bilayer is proportional to its concentration gradient across the bilayer and to its hydrophobicity and size.

If a substance carries a net charge, its movement across a membrane is influenced by both its concentration gradient and the **membrane potential**, the electric potential (voltage) across the membrane. The combination of these two forces, called the **electrochemical gradient**, determines the energetically favorable direction of movement of a charged molecule across a membrane (Figure 11-2). The electric potential that exists across most cellular membranes results from a small imbalance in the concentrations of positively and negatively charged ions on the two sides of the membrane. In Section 11.4, we discuss how this ionic imbalance, and the resulting potential, arise and are maintained.

FIGURE 11-2 Electrochemical gradients. Ions form a chemical gradient when there is a concentration difference across the membrane. Ions also form an electrical gradient across the membrane, created by the asymmetric distribution of positively and negatively charged ions across the membrane. The electrical gradient can be in the same or opposite direction from the chemical gradient. Together, they form an electrochemical gradient that serves as a force driving the transport of ions across the membrane.

Three Main Classes of Membrane Proteins Transport Molecules and Ions Across Cellular Membranes

As is evident from Figure 11-1, very few molecules and no ions can cross a pure phospholipid bilayer at appreciable rates by simple diffusion. Thus transport of most molecules into and out of cells requires the assistance of specialized membrane proteins. Even in the cases of some small uncharged polar molecules (e.g., urea, fatty acids) and certain gases, such as CO_2 (carbon dioxide) and NH_3 (ammonia), transport is frequently accelerated by specific proteins because simple diffusion is too slow to meet cellular needs.

All membrane transport proteins are transmembrane proteins containing multiple membrane-spanning segments that are generally α helices. By forming a protein-lined pathway across the membrane, transport proteins are thought to allow hydrophilic substances to move through the membrane without coming into

contact with its hydrophobic interior. Here we introduce the three main types of membrane transport proteins covered in this chapter (Figure 11-3).

FIGURE 11-3 Overview of membrane transport proteins. Gradients are indicated by triangles with the tip pointing toward lower concentration, electric potential, or both. **1** Channels permit movement of specific ions (or water) down their electrochemical gradient. **2** Transporters, which fall into three groups, facilitate movement of specific small molecules or ions. Uniporters transport a single type of molecule down its concentration gradient **2A**. Cotransport proteins (symporters, **2B**, and antiporters, **2C**) catalyze the movement of one molecule *against* its concentration gradient (black circles), driven by movement of one or more ions down an electrochemical gradient (red circles). **3** Pumps use the energy released by ATP hydrolysis to power movement of specific ions or small molecules (red circles) against their electrochemical gradient. Differences in the mechanisms of transport by these three major classes of proteins account for their varying rates of solute movement.

Channels transport water, specific ions, or small hydrophilic molecules across membranes *down* their concentration or electric potential gradients. Because this process requires transport proteins but not energy, it is sometimes referred to as *passive transport* or *facilitated diffusion*, but it is more properly called **facilitated transport**. Channels form a hydrophilic tube or passageway across

the membrane through which multiple water molecules or ions move simultaneously, single file, at a very rapid rate. Some channels are open much of the time; they are referred to as *nongated channels*. Most ion channels, however, open only in response to specific chemical or electrical signals. These channels are referred to as *gated channels* because a protein "gate" alternatively blocks the channel or moves out of the way to open the channel (see Figure 11-3). Like all transport proteins, channels are very selective for the type of molecule they transport.

Transporters (also called *carriers*) move a wide variety of ions and molecules across cellular membranes, but at a much slower rate than channels. Three types of transporters have been identified. *Uniporters* transport a single type of molecule *down* its concentration gradient. Glucose and amino acids cross the plasma membrane into most mammalian cells with the aid of uniporters. Collectively, channels and uniporters are sometimes called *facilitated transporters*, indicating movement down a concentration or electrochemical gradient.

In contrast, **antiporters** and **symporters** couple the movement of one type of ion or molecule *against* its concentration gradient with the movement of one or more different ions *down* its concentration gradient, in the same (symporter) or different (antiporter) directions. These proteins are often called **cotransporters** because

of their ability to transport two or more different solutes simultaneously.

ATP-powered pumps (or simply *pumps*) are ATPases, enzymes that catalyze hydrolysis of the terminal phosphoanhydride bond of ATP to produce ADP and Pi. These pumps use the energy of ATP hydrolysis to move ions or small molecules across a membrane *against* a chemical concentration gradient, an electric potential, or both. This process, referred to as **active transport**, is an example of a coupled chemical reaction (see Chapter 2). In this case, transport of ions or small molecules uphill against an electrochemical gradient, which requires energy, is coupled to the hydrolysis of ATP, which releases energy. The overall reaction — ATP hydrolysis and the uphill movement of ions or small molecules — is energetically favorable.

Both cotransporters and pumps rely on coupled reactions in which an energetically unfavorable reaction (i.e., the uphill movement of one type of molecule or ion) is coupled to an energetically favorable reaction (i.e., the downhill movement of another). Note, however, that the nature of the energy-supplying reaction driving active transport by these two classes of proteins differs. ATP pumps use energy from hydrolysis of ATP, whereas cotransporters use the energy stored in an electrochemical gradient. The latter process is sometimes referred to as *secondary active transport*.

Conformational changes are essential to the function of all transport proteins. Whereas channels switch between open and closed states, transporters and ATP-powered pumps undergo a cycle of conformational change exposing a binding site (or sites) to one side of the membrane in one conformation and to the other side in a second conformation, a process that has been termed the *alternating access model*. Determination of the high-resolution structures of transporters has revealed distinct molecular mechanisms by which alternating access is achieved. Because each cycle of conformational change within transporters and pumps results in the movement of only one substrate molecule (or, at most, a few), these proteins are characterized by relatively slow rates of transport, ranging from 10^0 to 10^4 ions or molecules per second (see Figure 11-3). In contrast, many ions can pass through an open channel without any further conformational change. For this reason, channels are characterized by very fast rates of transport, up to 10^8 ions per second.

Usually several different types of transport proteins work in concert within the plasma membrane of cells to achieve a physiological function. An example is seen in Figure 11-4, where an ATPase pumps Na^+ out of the cell and K^+ inward; this pump, which is found in virtually all metazoan cells, establishes the oppositely directed concentration gradients of Na^+ and K^+ ions across the plasma membrane (relatively high concentrations of K^+ inside and of Na^+ outside cells). These concentration gradients are used, for example, to power the import of amino acids by cotransporters. The human

genome encodes hundreds of different types of transport proteins that use the energy stored across the plasma membrane in the Na^+ concentration gradient and its associated electric potential to transport a wide variety of molecules into cells against their concentration gradients.

FIGURE 11-4 Multiple membrane transport proteins function together in the plasma membrane of metazoan cells. Gradients are indicated by triangles with the tip pointing toward lower concentration. The Na^+/K^+ ATPase in the plasma membrane uses energy released by ATP hydrolysis to pump Na^+ (red circles) out of the cell and K^+ (blue squares) into the cell; its action creates a concentration gradient of Na^+ that is greater outside the cell than inside, and one of K^+ that is greater inside than outside. Movement of positively charged K^+ ions out of the cell through membrane K^+ channels creates an electric potential across the plasma membrane — the cytosolic face is negative with respect to the extracellular face. A Na^+/lysine transporter, a typical sodium/amino acid cotransporter, moves two Na^+ ions together with one lysine from the extracellular medium into the cell. "Uphill" movement of the amino acid is powered by "downhill" movement of Na^+ ions, which in turn is powered both by the outside-greater-than-inside Na^+ concentration gradient and by the negative charge on the inside of the plasma membrane, which

attracts the positively charged Na^+ ions. The ultimate source of the energy to power amino acid uptake comes from the ATP hydrolyzed by the Na^+/K^+ ATPase, since this pump creates both the Na^+ ion concentration gradient and, via the K^+ channels, the membrane potential, which together power the influx of Na^+ ions.

Table 11-1 summarizes the four mechanisms by which small molecules and ions are transported across cellular membranes. In the next section, we consider some of the simplest membrane transport proteins, the uniporter responsible for the transport of glucose and the channel responsible for the transport of water.

TABLE 11-1 • Mechanisms for Transporting Ions and Small Molecules Across Cellular Membranes

Property	Simple Diffusion	Facilitated Transport	Cotransport[i]	Active Transport
Requires specific protein	–	+	+	+
Solute transported against its gradient	–	–	+	+
Coupled to ATP hydrolysis	–	–	–	+
Driven by	–	–	+	–

movement of a cotransported ion down its gradient				
Examples of molecules transported	O_2, CO_2, steroid hormones, many drugs	Glucose and amino acids (uniporters); ions and water (channels)	Glucose and amino acids (symporters); various ions and sucrose (antiporters)	Ions, small hydrophilic molecules, lipids (ATP-powered pumps)

[i]Also called *secondary active transport.*

KEY CONCEPTS OF SECTION 11.1

Overview of Transmembrane Transport

- Cellular membranes regulate the traffic of molecules and ions into and out of cells and their organelles. The rate of simple diffusion of a substance across a membrane is proportional to its concentration gradient and hydrophobicity.
- With the exception of gases (e.g., O_2 and CO_2) and small, uncharged, water-soluble molecules, most molecules cannot diffuse across a pure phospholipid bilayer at rates sufficient to meet cellular needs.
- Membrane transport proteins provide a hydrophilic passageway for molecules and ions to travel through a membrane that has a hydrophobic interior.
- Three classes of transmembrane proteins mediate transport of ions, sugars, amino acids, and other metabolites across cellular membranes: channels, transporters, and ATP-powered pumps (see Figure 11-2).
- Channels form a hydrophilic tube through which water or ions move *down* a concentration gradient, a process known as *facilitated transport*.
- Some channels are ungated, or open all the time, while other channels are gated, and open only in response to specific electrical or chemical signals (or to light in the case of the light-activated channels used in optogenetics, described in Chapters 4 and 23).

- Transporters fall into three groups. Uniporters transport a molecule down its concentration gradient (facilitated transport); symporters and antiporters couple movement of a substrate against its concentration gradient to the movement of a second substrate down its concentration gradient, a process known as *secondary active transport* or *cotransport* (see Table 11-1).
- ATP-powered pumps couple the movement of a substrate *against* its concentration gradient to ATP hydrolysis, a process known as *active transport*.
- Conformational changes are essential to the function of all membrane transport proteins; speed of transport depends on the number of substrate molecules or ions that can pass through a protein at once.
- The alternating access model describes the conformational changes that many transporters and pumps use to transport molecules across the membrane.

11.2 Facilitated Transport of Glucose and Water

Most animal cells use glucose as a substrate for ATP production; they usually employ a glucose uniporter to take up glucose from the blood or other extracellular fluid. Many cells use channel-like membrane transport proteins called *aquaporins* to increase the rate of water movement across their plasma membranes. Here we discuss the structure and function of these and other facilitated transporters.

Uniport Transport Is Faster and More Specific than Simple Diffusion

The transport of a single type of molecule, such as glucose or another small hydrophilic molecule, down a concentration gradient across a cellular membrane through a transport protein is known as **uniport**. Several features distinguish uniport from simple diffusion:

1. The rate of substrate movement by uniporters is far higher than simple diffusion through a pure phospholipid bilayer.
2. Because the transported molecule never enters the hydrophobic core of the phospholipid bilayer, its solubility in the lipid membrane is irrelevant.

3. Transport occurs via a limited number of uniporter molecules. Consequently, there is a maximum transport rate, V_{max}, which depends on the number of uniporters in the membrane. V_{max} is achieved when the concentration gradient across the membrane is very large and each uniporter is working at its maximal rate.
4. Transport is reversible, and the direction of transport changes if the direction of the concentration gradient changes.
5. Transport is specific. Each uniporter transports only a single type of molecule or a single group of closely related molecules. A measure of the affinity of a transporter for its substrate is the Michaelis constant, K_m, which is the concentration of substrate at which transport is half V_{max}.

These properties also apply to transport mediated by the other classes of proteins depicted in Figure 11-3.

One of the best understood uniporters is the glucose transporter called *GLUT1*, found in the plasma membrane of most mammalian cells. GLUT1 is especially abundant in the erythrocyte (red blood cell) plasma membrane. Because erythrocytes have a single membrane and no nucleus or other internal organelles (see Figure 10-7), it is relatively simple to isolate and purify the transport proteins in their plasma membranes. As a result, the properties of GLUT1 and many other transport proteins from mature erythrocytes have been extensively studied. In addition, the three-dimensional structure of human GLUT1 was solved in 2014, providing further

insights into the molecular details of GLUT1 function (see chapter opening image and Figure 11-6).

Figure 11-5 shows that glucose uptake by erythrocytes and liver cells exhibits kinetics similar to those of a simple enzyme-catalyzed reaction involving a single substrate. The kinetics of transport reactions mediated by other types of proteins are more complicated than those for uniporters. Nonetheless, all protein-assisted transport reactions occur faster than simple diffusion across the bilayer, are substrate-specific, and exhibit a maximal rate (V_{max}).

EXPERIMENTAL FIGURE 11-5 Cellular uptake of glucose mediated by GLUT proteins exhibits simple enzyme kinetics. The initial rate of glucose uptake, *v* (measured as micromoles per milliliter of cells per hour), in the first few seconds is plotted as a percentage of the maximum rate, V_{max}, against increasing glucose concentration in the extracellular medium. In this

experiment, the initial concentration of glucose in the cells is always zero. Both GLUT1, expressed by erythrocytes, and GLUT2, expressed by liver cells, catalyze glucose uptake. Like enzyme-catalyzed reactions, GLUT-facilitated uptake of glucose exhibits a maximum rate (V_{max}). K_{m} is the concentration at which the rate of glucose uptake is half maximal. GLUT2, with a K_{m} of about 20 mM (not shown), has a much lower affinity for glucose than GLUT1, with a K_{m} of about 1.5 mM.

The Low K_{m} of the GLUT1 Uniporter Enables It to Transport Glucose into Most Mammalian Cells

Like other uniporters, GLUT1 alternates between two conformational states: in one, a glucose-binding site faces the outside of the cell; in the other, a glucose-binding site faces the cytosol. The latter conformation has been solved at high resolution, as shown Figure 11-6a. Since the glucose concentration is usually higher in the extracellular medium (blood, in the case of erythrocytes) than in the cell, the GLUT1 uniporter generally catalyzes the net import of glucose from the extracellular medium into the cell. Figure 11-6b depicts the sequence of events during the unidirectional transport of glucose from the cell exterior inward to the cytosol as described by the alternating access model; note the conformational changes in several of the membrane-spanning α helices during this process. GLUT1 can also catalyze the net export of glucose from the cytosol to the extracellular medium when the

glucose concentration is higher inside the cell than outside. In the transition between the inward- and outward-facing states, the transporter is in an occluded conformation, in which the glucose-binding site is inaccessible to either the cytoplasm or the extracellular space.

FIGURE 11-6 The human GLUT1 uniporter transports glucose across cellular membranes. (a) Structural model (side view) of the full-length human GLUT1 protein in an inward-open conformation. The transporter consists of 12 transmembrane α-helical segments, which are organized into amino-terminal and carboxy-terminal domains, each of which consists of a pair of three transmembrane α helices, colored in orange, white, and blue. The amino-terminal and carboxy-terminal domains are connected by intracellular and extracellular α helices, which are colored green and purple, respectively. A section of a cut-open view of the surface electrostatic potential highlights the central cavity that transports glucose (red) across the membrane. The colors represent the hydrophobicity of the amino acids, with hydrophobic in yellow and hydrophilic in blue. (b) A working model for GLUT1. In this alternating access model, the outward-open conformation of GLUT1 binds glucose (step 1) and moves to a ligand-bound occluded conformation (step 2) before changing to its inward-open conformation (step 3) when it delivers glucose to the cytoplasm, then moves through a ligand-free occluded conformation (step 4) before beginning another round of glucose transport from outside to inside the cell. If the concentration of glucose is higher

inside the cell than outside, the cycle will work in reverse (step 4 → step 1), resulting in net movement of glucose out of the cell. The orange helices correspond to helices 1, 4, 7, and 10 in (a). The actual conformational changes are probably smaller than those depicted here.

[Part (a) data from D. Deng et al., 2014, *Nature* **510**:121–125, PDB ID 4pyp.]

The kinetics of the unidirectional transport of glucose from the outside of a cell inward via GLUT1 can be described by the same type of equation used to describe a simple enzyme-catalyzed chemical reaction. For simplicity, let's assume that the substrate (glucose), S, is present initially only on the outside of the cell; this can be achieved experimentally by first incubating cells in a medium lacking glucose so that their internal stores are depleted. In this case, we can write

$$\mathrm{S_{out}} + \mathrm{GLUT1} \overset{K_\mathrm{m}}{\rightleftharpoons} \mathrm{S_{out}} - \mathrm{GLUT1} \overset{V_\mathrm{max}}{\rightleftharpoons} \mathrm{S_{in}} + \mathrm{GLUT1}$$

where $\mathrm{S_{out}} - \mathrm{GLUT1}$ represents GLUT1 in the outward-facing conformation with a bound glucose. This equation is similar to the one describing the path of a simple enzyme-catalyzed reaction in which the protein binds a single substrate and then transforms it into a different molecule. Here, however, no chemical modification of the GLUT1-bound glucose molecule occurs; rather, it is moved across a cellular membrane. Nonetheless, the kinetics of this transport reaction are similar to those of simple enzyme-catalyzed reactions, and we can use the same derivation as that of the

Michaelis–Menten equation in Chapter 3 to derive the following expression for v_0, the initial transport rate for S into the cell catalyzed by GLUT1:

$$v_0 = \frac{V_{\max}}{1 + \frac{K_{\mathrm{m}}}{C}} \tag{11-1}$$

where C is the concentration of $\mathrm{S}_{\mathrm{out}}$ (initially, the concentration of $\mathrm{S}_{\mathrm{in}} = 0$). $V_{\max}$, the rate of transport when all molecules of GLUT1 contain a bound S, occurs at an infinitely high $\mathrm{S}_{\mathrm{out}}$ concentration. The lower the value of K_{m}, the more tightly the substrate binds to the transporter. Equation 11-1 describes the curve for glucose uptake by erythrocytes shown in Figure 11-4 as well as similar curves for other uniporters.

For GLUT1 in the human erythrocyte membrane, the K_{m} for glucose transport is 1.5 mM. Thus when the extracellular glucose concentration is 1.5 mM, roughly half the GLUT1 transporters with outward-facing binding sites will have a bound glucose, and transport will occur at 50 percent of the maximal rate. Blood glucose is normally 5 mM, so the erythrocyte glucose transporter is usually functioning at 77 percent of its maximal rate, as can be seen from Equation 11-1. The GLUT1 transporter (or the very similar GLUT3 glucose transporter) is expressed by all body cells that need to take up glucose from the blood continuously at high rates. The rate of

glucose uptake by such cells remains high regardless of small changes in the concentration of blood glucose because the blood concentration remains much higher than the K_m and the intracellular glucose concentration is kept low as a result of active metabolism. Of note, GLUT1 expression is elevated in many malignant cancers, consistent with the need for glucose as a source of energy for rapidly dividing cancer cells.

In addition to transporting glucose, GLUT1 transports the isomeric sugars D-mannose and D-galactose, which differ from D-glucose in their configuration at only one carbon atom, at measurable rates. However, the K_m for glucose (1.5 mM) is much lower than it is for D-mannose (20 mM) or D-galactose (30 mM). Thus GLUT1 is quite specific, having a much higher affinity (indicated by a lower K_m) for its normal substrate D-glucose than for other substrates.

GLUT1 accounts for 2 percent of the protein in the plasma membrane of erythrocytes. After glucose is transported into the erythrocyte, it is rapidly phosphorylated, forming glucose-6-phosphate, which cannot leave the cell. Because this reaction, the first step in the metabolism of glucose (see Figure 12-3), is rapid and occurs at a constant rate, the intracellular concentration of glucose is kept low even when glucose is imported from the extracellular environment. Consequently, the concentration gradient of glucose (outside greater than inside the cell) is kept sufficiently high to

support continuous, rapid import of additional glucose molecules and provide sufficient glucose for cellular metabolism.

The Human Genome Encodes a Family of Sugar-Transporting GLUT Proteins

The human genome encodes at least 14 highly homologous *GLUT proteins*, GLUT1–GLUT14. All are thought to contain 12 membrane-spanning α helices, suggesting that they evolved from a single ancestral transport protein. In the human GLUT1 protein, the transmembrane α helices are predominantly hydrophobic; several helices, however, bear amino acid residues (e.g., serine, threonine, asparagine, and glutamine) whose side chains can form hydrogen bonds with the hydroxyl groups on glucose. These residues are thought to form the inward-facing and outward-facing glucose-binding sites in the interior of the protein (see Figure 11-5).

The structures of all GLUT isoforms are thought to be quite similar, and all of them transport sugars. Nonetheless, the isoforms differ in their expression in various cell types, in the regulation of their numbers on cell surfaces, and in their functional properties. By using isoforms with different properties, different body cells are able to regulate glucose metabolism differently and at the same time allow a constant concentration of glucose in the blood to be maintained. For instance, GLUT3 is found in neuronal cells of the

brain. Neurons depend on a constant influx of glucose for metabolism, and the low K_m of GLUT3 for glucose (1.5 mM), like that of GLUT1, ensures that these cells incorporate glucose from brain extracellular fluids at a high and constant rate.

GLUT2, expressed in liver cells and in the insulin-secreting β islet cells of the pancreas, has a K_m of ~20 mM, about 13 times higher than the K_m of GLUT1. As a result, when blood glucose rises after a meal from its basal level of 5 mM to 10 mM or so, the rate of glucose influx will almost double in GLUT2-expressing cells, whereas it will increase only slightly in GLUT1-expressing cells (see Figure 11-5). In the liver, the excess glucose brought into the cell is stored as the polymer glycogen. In β islet cells, the rise in glucose triggers secretion of the hormone insulin (see Figure 21-1b), which in turn lowers blood glucose by increasing glucose uptake and metabolism in muscle (see Figure 15-32) and by inhibiting glucose production in the liver. Indeed, inactivation of GLUT2 in pancreatic β islet cells prevents insulin secretion even when levels of glucose are high and disrupts the regulated expression of glucose-sensitive genes in liver cells (hepatocytes).

Another GLUT isoform, GLUT4, is expressed only in fat and muscle cells. These cells respond to insulin by increasing their uptake of glucose, thereby removing glucose from the blood. In the absence of insulin, GLUT4 resides in intracellular membranes, not the plasma membrane, and is unable to facilitate glucose uptake from the

extracellular fluid. By a process detailed in Figure 21-2, insulin causes these GLUT4-rich internal membranes to fuse with the plasma membrane, increasing the number of GLUT4 molecules present on the cell surface and thus the rate of glucose uptake. This is one principal mechanism by which insulin lowers blood glucose; defects in the movement of GLUT4 to the plasma membrane are one of the causes of adult-onset, or type II, diabetes, a disease marked by continuously high blood glucose.

GLUT5 is the only GLUT protein with a high specificity (preference) for fructose. Its principal site of expression is the apical membrane of intestinal epithelial cells, where it transports dietary fructose from the intestinal lumen to the inside of the cells.

Transport Proteins Can Be Studied Using Artificial Membranes and Recombinant Cells

There are a variety of approaches to studying the intrinsic properties of transport proteins, such as the V_{max} and K_{m} parameters and the key residues responsible for binding. Most cellular membranes contain many different types of transport proteins but a relatively low concentration of any particular one, which makes functional studies of a single protein difficult. To facilitate such studies, researchers use two approaches to enrich a

transport protein of interest so that it predominates in the membrane: purification and insertion into artificial membranes and overexpression in recombinant cells.

In the first approach, a specific transport protein is extracted from its membrane with detergent and purified. Although transport proteins can be isolated from membranes and purified, their functional properties (i.e., their role in the movement of substrates across membranes) can be studied only when they are associated with a membrane. Thus the purified proteins are usually reincorporated into membranes composed of a pure phospholipid bilayer, such as liposomes (see Figure 10-3). The rate of substrate transport across such membranes can be readily measured.

Alternatively, the gene encoding a specific transport protein can be expressed at high levels in a cell type that normally does not express it. The difference between the transport rate of a substance by the transfected cells and by control nontransfected cells will be due to the expressed transport protein. In these systems, the functional properties of the various membrane proteins can be examined without ambiguity caused, for instance, by partial protein denaturation during isolation and purification procedures. As an example, overexpressing GLUT1 in lines of cultured fibroblasts increases their rate of uptake of glucose severalfold, and expression of mutant GLUT1 proteins with specific amino acid alterations can identify residues important for substrate binding.

Osmotic Pressure Causes Water to Move Across Membranes

The life of all organisms depends on the movement of water into and out of cells. The **aquaporins** are a family of membrane channel proteins that allow water and a few other small uncharged molecules, such as glycerol, to cross cellular membranes efficiently. Before discussing these transport proteins, we need to review osmosis, the force that powers the movement of water across membranes.

Water spontaneously moves downhill across a semipermeable membrane from a solution of lower solute concentration (relatively high water concentration) to one of higher solute concentration (relatively low water concentration), a process termed **osmosis**, or *osmotic flow*. In effect, osmosis is equivalent to diffusion of water across a semipermeable membrane. *Osmotic pressure* is defined as the hydrostatic pressure required to stop the net flow of water across a membrane separating solutions of different water concentrations (Figure 11-7). In other words, osmotic pressure balances the entropy-driven thermodynamic force of the water concentration gradient. In this context, a "membrane" may be a layer of cells or a plasma membrane that is permeable to water but not to the solutes it contains. The osmotic pressure is directly proportional to the difference in the concentrations of the total numbers of solute molecules on the two sides of the membrane. For example, a 0.5 M

NaCl solution is actually 0.5 M Na^+ ions and 0.5 M Cl^- ions and has a similar osmotic pressure as a 1 M solution of glucose or sucrose.

FIGURE 11-7 Osmotic pressure. Solutions A and B are separated by a membrane that is permeable to water but impermeable to all solutes. If C_B (the total concentration of solutes in solution B) is greater than C_A, water will tend to flow across the membrane from solution A to solution B. Osmotic pressure π is the hydrostatic pressure that would have to be applied to solution B to prevent this water flow. From the van't Hoff equation, osmotic pressure is given by $\pi = RT(C_B - C_A)$, where *R* is the gas constant and *T* is the absolute temperature.

The movement of water across the plasma membrane determines the volume of an individual cell, which must be regulated to avoid damage to the cell. Small changes in extracellular osmotic conditions cause most animal cells to swell or shrink rapidly. When placed in a *hypotonic* solution (i.e., one in which the concentration of non-membrane-penetrating solutes is lower than in the cytosol), animal cells swell owing to the osmotic flow of water inward. Conversely, when placed in a *hypertonic* solution (i.e., one in which the concentration of non-membrane-penetrating solutes is higher than in the cytosol), animal cells shrink as cytosolic water leaves the cell by osmotic flow. Consequently, cultured animal cells must be maintained in an *isotonic* medium, which has a solute concentration, and thus osmotic strength, similar to that of the cell cytosol.

In vascular plants, water and minerals are absorbed from the soil by the roots and move up the plant through conducting tubes (the xylem); water loss from the plant, mainly by evaporation from the leaves, drives this movement of water. Unlike animal cells, plant, algal, fungal, and bacterial cells are surrounded by a rigid cell wall, which resists the expansion of the volume of the cell when the intracellular osmotic pressure increases. Without such a wall, animal cells expand when internal osmotic pressure increases; if that pressure rises too much, the cells burst like overinflated balloons. Because of the cell wall, the osmotic influx of water that occurs when plant cells are placed in a hypotonic solution (even pure water) leads to an increase in intracellular pressure, but not in cell volume.

In plant cells, the concentration of solutes (e.g., sugars and salts) is usually higher in the vacuole (see Figure 1-13a) than in the cytosol, which in turn has a higher solute concentration than the extracellular space. The osmotic pressure generated by the entry of water into the cytosol and then into the vacuole, called *turgor pressure*, pushes the cytosol and the plasma membrane against the resistant cell wall. Plant cells can harness this pressure to help them stand upright and grow. Cells elongate during growth by means of a process induced by hormones: a defined region of the cell wall loosens and then water flows into the vacuole, increasing its size and thus the size of the cell. ■

Although most protozoans (like animal cells) do not have a rigid cell wall, many contain a *contractile vacuole* that permits them to avoid bursting from osmotic pressure. A contractile vacuole takes up water from the cytosol and, unlike a plant vacuole, periodically discharges its contents through fusion with the plasma membrane. Thus even though water continuously enters the protozoan cell by osmotic flow, the contractile vacuole prevents too much water from accumulating in the cell and swelling it to the bursting point.

Aquaporins Increase the Water Permeability of Cellular Membranes

The natural tendency of water to flow across cellular membranes as a result of osmotic pressure raises an obvious question: Why don't the cells of freshwater animals burst in water? Frogs, for example, lay their eggs in pond water (a hypotonic solution), but frog oocytes and eggs do not swell with water even though their internal salt (mainly KCl) concentration is comparable to that of other cells ($\sim$150 mM KCl). These observations were what first led investigators to suspect that the plasma membranes of most cell types, but not of frog oocytes, contain water-channel proteins that accelerate the osmotic flow of water. The finding that injection of the mRNA encoding the aquaporin channel protein into frog eggs caused them to burst in fresh water demonstrated that aquaporins are sufficient to increase the permeability of cells to water.

Aquaporin channels are selective for water molecules, which they transport in either direction depending on the osmotic gradient. A tetramer of identical 28-kDa subunits (Figure 11-8a), each subunit contains six membrane-spanning α helices that form a central pore through which water can move (Figure 11-8b, c). The ∼2-nm-long channel, or pore, at the center of each monomer is only 0.28 nm in diameter — only slightly larger than the diameter of a water molecule. The molecular sieving properties of the channel are determined by several conserved, hydrophilic amino acid residues whose side-chain and carbonyl groups extend into the middle of the channel and by a relatively hydrophobic wall that lines one side of the channel. Several water molecules can move simultaneously through the channel, each molecule sequentially forming specific hydrogen bonds with the channel-lining amino acids and displacing another water molecule downstream. Aquaporins do not undergo conformational changes during water transport, so they transport water orders of magnitude faster than GLUT1 transports glucose. The formation of hydrogen bonds between the oxygen atom of water and the amino groups of two amino acid side chains ensures that only uncharged water (i.e., H_2O, but not H_3O^+) passes through the channel; the orientations of the water molecules in the channel prevent protons from jumping from one to the next and thus prevent the net movement of protons through the channel. As a consequence, ionic gradients are maintained across membranes even when water is flowing across them through aquaporins.

FIGURE 11-8 Structure of an aquaporin. (a) Structural model of the tetrameric protein comprising four identical subunits. Each subunit forms a water channel, as seen in this view looking down on the protein from the exoplasmic side. One of the monomers is shown as a water-accessible surface model, in which the pore entrance can be seen. (b) Schematic diagram of the topology of a single aquaporin subunit in relation to the membrane. Three pairs of homologous transmembrane α helices (A and A', B and B', and C and C') are oriented in the opposite direction with respect to the membrane and are connected by two hydrophilic loops containing short non-membrane-spanning helices and conserved asparagine (Asn) residues. The loops bend into the cavity formed by the six transmembrane helices, meeting in the middle to form part of the water-selective gate. (c) Side view of the pore in a single aquaporin subunit, in which several water molecules (blue spheres) are seen within the 2-nm-long water-selective gate that separates the water-filled cytosolic and extracellular vestibules. The gate contains highly conserved hydrophilic amino acid residues whose side chains form hydrogen bonds with transported water molecules. The amino acids lining the pore are colored from hydrophilic (blue) to hydrophobic (yellow). The arrangement of these hydrogen bonds and the narrow pore diameter of 0.28 nm prevent passage of protons (i.e., H_3O^+) or other ions.

[Data from H. Sui et al., 2001, *Nature* **414**:872, PDB ID 1j4n.]

Mammals express a family of aquaporins; 14 such genes are known in humans. Aquaporin 1 is expressed in abundance in

erythrocytes, and the homologous aquaporin 2 is found in the kidney epithelial cells that resorb water from the urine, thus controlling the amount of water in the body. The activity of aquaporin 2 is regulated by vasopressin, also called *antidiuretic hormone*, in a manner that resembles the regulation of GLUT4 activity in fat and muscle. When the cells are in their resting state and water is being excreted to form urine, aquaporin 2 is sequestered in intracellular vesicle membranes and so is unable to import water into the cell. When the polypeptide hormone vasopressin binds to the cell-surface vasopressin receptor, it activates a signaling pathway using cAMP as the intracellular signal (detailed in Chapter 15) that causes these aquaporin 2–containing vesicles to fuse with the plasma membrane, increasing the rate of water uptake and return to the circulation. Inactivating mutations in either the vasopressin receptor or the aquaporin 2 gene cause *diabetes insipidus*, a disease marked by excretion of large volumes of dilute urine. This finding demonstrates that the level of aquaporin 2 is rate limiting for water resorption from urine being formed by the kidney. ■

Other members of the aquaporin family transport hydroxyl-containing molecules such as glycerol rather than water. Human aquaporin 3, for instance, transports glycerol and is similar in amino acid sequence and structure to the *Escherichia coli* glycerol transport protein GlpF.

KEY CONCEPTS OF SECTION 11.2

Facilitated Transport of Glucose and Water

- Protein-catalyzed transport of biological solutes across a membrane occurs much faster than simple diffusion, exhibits $V_{\max}$ when the limited number of transporter molecules are saturated with substrate, and is highly specific for substrate (see Figure 11-4).
- Uniport proteins, such as the glucose transporters (GLUTs), are thought to shuttle between two conformational states, one in which the substrate-binding site faces outward and one in which the binding site faces inward (see Figure 11-5).
- All members of the GLUT protein family transport sugars and have similar structures. Differences in their K_{m} values, expression in different cell types, and substrate specificities are important for proper sugar metabolism in the body.
- Two common experimental systems for studying the functions of transport proteins are liposomes containing a purified transport protein and cells transfected with the gene encoding a particular transport protein.
- Most cellular membranes are semipermeable, more permeable to water than to ions or most other solutes. Water moves by osmosis across membranes from a solution of lower solute concentration to one of higher solute concentration.
- The rigid cell wall surrounding plant cells prevents their swelling and leads to generation of turgor pressure in response to the osmotic influx of water.
- Aquaporins are water-channel proteins that specifically increase the permeability of cellular membranes to water (see Figure 11-8).
- Aquaporin 2 in the plasma membrane of certain kidney cells is essential for resorption of water from urine being formed; the absence of aquaporin 2 leads to the medical condition diabetes insipidus.

11.3 ATP-Powered Pumps and the Intracellular Ionic Environment

In the previous sections, we focused on transport proteins that move molecules down their concentration gradients (facilitated transport). Here we focus our attention on the class of proteins — the ATP-powered pumps — that use the energy released by hydrolysis of the terminal phosphoanhydride bond of ATP to transport ions and various small molecules across membranes *against* their concentration gradients. All ATP-powered pumps are transmembrane proteins with one or more binding sites for ATP located on subunits or segments of the protein that face the cytosol. These proteins are ATPases, but they normally do not hydrolyze ATP into ADP and P_i unless ions or other molecules are simultaneously transported. Because of this tight *coupling* between ATP hydrolysis and transport, the energy stored in the phosphoanhydride bond is not dissipated as heat, but rather is used to move ions or other molecules uphill against an electrochemical gradient.

There Are Four Main Classes of ATP-Powered Pumps

The general structures of the four classes of ATP-powered pumps are depicted in Figure 11-9, with specific examples in each class listed below the figure. Note that the members of three of the classes

(P, F, and V) transport only ions, as do some members of the fourth class, the ABC superfamily. Most members of the ABC superfamily, however, transport small molecules such as amino acids, sugars, peptides, lipids, and many types of drugs.

FIGURE 11-9 The four classes of ATP-powered transport proteins. The locations of specific examples are indicated below each class. (a) P-class pumps are composed of two catalytic α subunits, which become phosphorylated as part of the transport cycle. Two β subunits, present in some of these pumps, may regulate transport. Only one α and one β subunit are depicted here, from Na^+/K^+ ATPase, with the three red circles representing Na^+ ion binding sites and the two light green squares representing K^+ ion binding sites. (b, c) V-class and F-class pumps are not phosphorylated, and almost all transport only protons. *V-class pumps* couple ATP hydrolysis to transport protons against a concentration gradient, whereas *F-class pumps* normally operate in the reverse direction and use the energy in a proton concentration or voltage gradient to synthesize ATP. (d) All members of the large ABC superfamily of proteins contain two transmembrane (T) domains and two cytosolic ATP-binding (A) domains, which couple ATP hydrolysis to solute movement. These core domains

are present as separate subunits in some ABC proteins (as depicted here) but are fused into a single polypeptide in other ABC proteins.

[Information from S. Sharma et al., 2019, *J. Biol. Chem.* **294**:6439; C. Toyoshima et al., 2000, *Nature* **405**:647; D. McIntosh, 2000, *Nat. Struct. Biol.* **7**:532; and H. Okamoto and M. Futai, 2013, *Encyclopedia of Biophysics*, https://doi.org/10.1007/978-3-642-16712-6_203.]

All **P-class pumps** possess two identical catalytic α subunits, each of which contains an ATP-binding site. Most also have two smaller β subunits, which usually have regulatory functions. During transport, at least one of the α subunits becomes phosphorylated (hence the name "P" class), and the transported ions move through the phosphorylated subunit. The amino acid sequences around the phosphorylated residues are homologous in different pumps. This class includes the Na^+/K^+ ATPase in the plasma membrane, which generates the low cytosolic Na^+ and high cytosolic K^+ concentrations typical of animal cells (see Figure 11-3). Certain Ca^{2+} ATPases pump Ca^{2+} ions out of the cytosol into the external medium; others pump Ca^{2+} from the cytosol into the endoplasmic reticulum or into the specialized ER called the *sarcoplasmic reticulum (SR)* that is found in muscle cells. Another member of the P class, the gastric proton pump, is found in acid-secreting cells of the mammalian stomach; the gastric proton pump transports protons (H^+ ions) out of and K^+ ions into the cell. The recently solved crystal structure of this pump yielded important insights into the binding sites of drugs that are used to treat diseases of damage caused by gastric acid such as gastric ulcers and reflux esophagitis.

The structures of *V-class* and *F-class pumps* are similar to one another but are unrelated to, and more complicated than, those of P-class pumps. V- and F-class pumps contain several different transmembrane and cytosolic subunits. Virtually all known V and F pumps transport only protons and do so in a process that does not require phosphorylation. V-class pumps generally function to generate the low pH of plant vacuoles and of lysosomes and other acidic vesicles in animal cells by pumping protons from the cytosolic to the exoplasmic face of the membrane against a proton electrochemical gradient. In contrast, the proton pumps that generate and maintain the electric potential across the plasma membrane in plant, fungal, and many bacterial cells belong to the P-class pumps.

F-class pumps are found in bacterial plasma membranes and in mitochondria and chloroplasts. In contrast to V-class pumps, they generally function as reverse proton pumps, in which protons move from the exoplasmic to the cytosolic face of the membrane *down* the proton electrochemical gradient, in the energetically favored direction. The energy released is used to power the energetically unfavorable synthesis of ATP from ADP and P_i. Because of their importance in ATP synthesis in chloroplasts and mitochondria, F-class proton pumps, commonly called *ATP synthases,* are treated separately in Chapter 12 (see Figure 12-27).

The final class of ATP-powered pumps is a large family with multiple members that are more diverse in function than those of the other classes. Referred to as the **ABC** (*A*TP-*b*inding *c*assette) **superfamily**, this class includes several hundred different transport proteins found in organisms ranging from bacteria to humans. As detailed below, some of these transport proteins were first identified as multidrug-resistance proteins that, when overexpressed in cancer cells, export anticancer drugs and render tumors resistant to their action. Each ABC protein is specific for a single substrate or group of related substrates, which may be ions, sugars, amino acids, phospholipids, cholesterol, peptides, polysaccharides, or even proteins. All ABC membrane transport proteins share a structural organization consisting of four core domains: two transmembrane (T) domains, which form the passageway through which transported molecules cross the membrane, and two cytosolic ATP-binding (A) domains. In some ABC proteins, mostly those in bacteria, the core domains are present as four separate polypeptides; in others, the core domains are fused into one or two multidomain polypeptides. ATP binding and hydrolysis drives the transport process in most ABC membrane transporters. However, the energy from ATP binding and hydrolysis can also be used to regulate the opening and closing of a continuous channel, as described below for the cystic fibrosis transmembrane conductance regulator protein (CFTR).

ATP-Powered Ion Pumps Generate and Maintain Ionic Gradients Across Cellular Membranes

The specific ionic composition of the cytosol usually differs greatly from that of the surrounding extracellular fluid. In virtually all cells — including microbial, plant, and animal cells — the cytosolic pH is kept near 7.2 *regardless* of the extracellular pH. In the most extreme case, there is a 1-million-fold difference in H^+ concentration between the cytosol of the epithelial cells lining the stomach and the stomach contents after a meal. Furthermore, the cytosolic concentration of K^+ is much higher than that of Na^+. In both invertebrates and vertebrates, the concentration of K^+ is 20–40 times higher in the cytosol than in the blood, while the concentration of Na^+ is 8–12 times lower in the cytosol than in the blood (Table 11-2).

TABLE 11-2 • Typical Intracellular and Extracellular Ion Concentrations

Ion	Cell (mM)	Seawater (mM)
Squid Giant Axon (marine invertebrate)[i]		
K^+	400	10
Na^+	50	440

Cl^-	40–150	560
Ca^{2+}	0.0003	10
X^-[ii]	300–400	5–10
Mammalian Cell (vertebrate)	**Cell (mM)**	**Blood (mM)**
K^+	139	4
Na^+	12	145
Cl^-	4	116
HCO_3^-	12	29
X^-	138	9
Mg^{2+}	0.8	1.5
Ca^{2+}	<0.0002	1.8

[i]The large nerve axon of the squid has been widely used in studies of the mechanism of conduction of electric impulses.

[ii]X^- represents proteins, which have a net negative charge at the neutral pH of blood and cells.

Some Ca^{2+} in the cytosol is bound to the negatively charged groups in ATP and in proteins and other molecules, but it is the concentration of unbound (or "free") Ca^{2+} that is critical to its functions in signaling pathways and muscle contraction. The concentration of free Ca^{2+} in the cytosol is generally less than 0.2 micromolar ($2 \times 10^{-7}\mu M$), a thousand or more times lower than

that in the blood. Plant cells and many microorganisms maintain similarly high cytosolic concentrations of K^+ and low concentrations of Ca^{2+} and Na^+, even if the cells are cultured in very dilute salt solutions.

The ion pumps discussed in this section are largely responsible for establishing and maintaining the typical ionic gradients observed across the plasma and intracellular membranes. In carrying out this task, cells expend considerable energy. For example, up to 25 percent of the ATP produced by nerve and kidney cells is used for ion transport, and human erythrocytes consume up to 50 percent of their available ATP for this purpose; in both cases, most of this ATP is used to power the Na^+/K^+ pump (see Figure 11-3). In neurons, the pump maintains Na^+ and K^+ gradients that are essential for conducting electrical signals rapidly and efficiently, as we detail in Chapter 23. Certain enzymes required for protein synthesis in all cells require a high K^+ concentration and are inhibited by high concentrations of Na^+; these enzymes would cease to function without the operation of the Na^+/K^+ pump. In cells treated with poisons that inhibit the production of ATP (e.g., 2,4-dinitrophenol in aerobic cells), the pumping stops, and the ion concentrations inside the cell gradually approach those of the exterior environment as ions spontaneously move through channels in the plasma membrane down their electrochemical gradients. Eventually the treated cells die, partly because protein synthesis requires a high concentration of K^+ ions and partly because, in the absence of a Na^+

gradient across the plasma membrane, a cell cannot import certain nutrients such as amino acids (see Figure 11-3). Studies on the effects of such poisons provided early evidence for the existence and significance of ion pumps.

Muscle Relaxation Depends on Ca^{2+} ATPases That Pump Ca^{2+} from the Cytosol into the Sarcoplasmic Reticulum

In skeletal muscle cells, Ca^{2+} ions are concentrated and stored in the sarcoplasmic reticulum (SR), a specialized type of endoplasmic reticulum (ER). The release (via ion channels) of stored Ca^{2+} ions from the SR lumen into the cytosol causes muscle contraction, as discussed in Chapter 17. A P-class Ca^{2+} ATPase located in the SR membrane pumps Ca^{2+} from the cytosol back into the lumen of the SR, thereby inducing muscle relaxation.

The activity of the muscle Ca^{2+} ATPase increases as the free Ca^{2+} concentration in the cytosol rises. In the cytosol of muscle cells, the free Ca^{2+} concentration ranges from 0.1 μM (resting cells) to more than 1 μM (contracting cells), whereas the *total* Ca^{2+} concentration in the SR lumen can be as high as 10 mM. The lumen of the SR contains two abundant proteins, calsequestrin and the so-called

high-affinity Ca^{2+}-binding protein, each of which binds multiple Ca^{2+} ions at high affinity. By binding much of the Ca^{2+} in the SR lumen, these proteins reduce the concentration of "free" Ca^{2+} ions inside the SR. This reduction, in turn, reduces the Ca^{2+} concentration gradient between the cytosol and the SR lumen and consequently reduces the energy needed to pump Ca^{2+} ions into the SR from the cytosol.

In skeletal muscle cells, the calcium pump in the SR membrane works in concert with a similar Ca^{2+} pump located in the plasma membrane to ensure that the cytosolic concentration of free Ca^{2+} in resting muscle remains at or below 0.1 μM. As the Ca^{2+} pump in the SR membrane moves Ca^{2+} into the SR lumen, the Ca^{2+} pump in the plasma membrane moves Ca^{2+} out of the cell. The activity of plasma-membrane Ca^{2+} ATPases is regulated by *calmodulin*, a cytosolic Ca^{2+}-binding protein (see Figure 3-34). A rise in cytosolic Ca^{2+} induces the binding of Ca^{2+} ions to calmodulin, which triggers activation of the Ca^{2+} ATPase. In this way, free Ca^{2+} ion concentration is coordinately regulated in the muscle cell cytoplasm and the SR lumen.

The Mechanism of Action of the Ca^{2+} Pump Is Known in Detail

Because the calcium pump constitutes more than 80 percent of the integral membrane protein in muscle SR membranes, it is easily purified and has been studied extensively. The three-dimensional structure of this protein has been determined in several conformational states, representing different steps in the pumping process. These structures have revealed much about its mechanism of action, which serves as a model for understanding many P-class ATPases.

The current model for the mechanism of action of the Ca^{2+} ATPase in the SR membrane proposes that the ATPase passes through multiple conformational states. The Ca^{2+} ATPase has two binding sites for Ca^{2+}, located in the center of the membrane-spanning domain. For simplicity, we group the multiple conformation states into E1 states, in which the two binding sites face the cytosol, and E2 states, in which these binding sites face the exoplasmic face of the membrane, pointing into the lumen of the SR. The coupling of ATP hydrolysis with ion pumping requires several conformational changes in the protein that must occur in a defined order, as shown in Figure 11-10. When the protein is in the E1 conformation, two Ca^{2+} ions bind to two high-affinity binding sites accessible from the cytosolic side; even though the cytosolic Ca^{2+} concentration is low (see Table 11-2), calcium ions still fill these sites.

Next an ATP binds to a site on the cytosolic surface (step **1**). The bound ATP is hydrolyzed to ADP in a reaction that requires Mg^{2+},

and the liberated phosphate is transferred to a specific aspartate residue in the protein, forming the high-energy acyl phosphate bond denoted by E1 $\sim$ P (step **2**). The protein then undergoes a conformational change that generates E2, in which the affinity of the two Ca^{2+}-binding sites is reduced (shown in detail in the next figure) and in which these sites are now accessible to the SR lumen (step **3**). The free energy of hydrolysis of the aspartyl-phosphate bond in E1 $\sim$ P is greater than that in E2–P, and this reduction in the free energy of the aspartyl-phosphate bond can be said to power the E1 $\rightarrow$ E2 conformational change.

The Ca^{2+} ions spontaneously dissociate from the binding sites to enter the SR lumen because even though the Ca^{2+} concentration there is higher than in the cytosol, it is lower than the K_d for Ca^{2+} binding in the low-affinity state (step **4**). Finally, the aspartyl-phosphate bond is hydrolyzed (step **5**). This dephosphorylation, coupled with subsequent binding of cytosolic Ca^{2+} to the high-affinity E1 Ca^{2+}-binding sites, stabilizes the E1 conformational state relative to E2; furthermore, it can be said to power the E2 $\rightarrow$ E1 conformational change (step **6**). Now E1 is ready to transport two more Ca^{2+} ions. Thus the cycle is complete, and hydrolysis of one phosphoanhydride bond in ATP has powered the pumping of two Ca^{2+} ions against a concentration gradient into the SR lumen.

Much structural and biophysical evidence supports the model depicted in Figure 11-10. For instance, the muscle calcium pump has

been isolated with phosphate linked to the key aspartate residue, and spectroscopic studies have detected slight alterations in protein conformation during the E1 → E2 conversion. The two phosphorylated states can also be distinguished biochemically; addition of ADP to phosphorylated E1 results in synthesis of ATP, the reverse of step **2**, whereas addition of ADP to phosphorylated E2 does not. Each principal conformational state of the reaction cycle can also be characterized by a different susceptibility to various proteolytic enzymes such as trypsin.

FIGURE 11-10 Operational model of the Ca^{2+} ATPase in the SR membrane of skeletal muscle cells. Only one of the two catalytic α subunits of this P-class pump is depicted. E1 and E2 are alternate conformations of the protein in which the Ca^{2+}-binding sites are accessible from the cytosolic and exoplasmic (SR lumen) faces of the membrane, respectively. An ordered sequence of steps, as diagrammed here, is essential for coupling ATP hydrolysis with the transport of Ca^{2+} ions across the membrane. In the figure, ~P indicates a high-energy aspartyl-phosphate bond; –P indicates a low-energy bond. Because the affinity of Ca^{2+} for the cytosolic-facing binding sites in E1 is 1000-fold greater than its affinity for the exoplasmic-facing sites in E2, this pump transports Ca^{2+} unidirectionally

from the cytosol to the SR lumen. See the text and Figure 11-11 for more detail. See C. Toyoshima and G. Inesi, 2004, *Annu. Rev. Biochem.* **73**:269–292.

Figure 11-11b shows the three-dimensional structure of the Ca^{2+} pump in the E1 state. As can be seen in Figure 11-11c, the 10 membrane-spanning α helices in the catalytic subunit form the passageway through which Ca^{2+} ions move. Amino acids in four of these helices form the two high-affinity E1 Ca^{2+}-binding sites (Figure 11-11a, *left*). One site is formed from negatively charged oxygen atoms from the carboxyl groups (COO^-) of glutamate and aspartate side chains, as well as from bound water molecules. The other site is formed from side- and main-chain oxygen atoms. Thus as Ca^{2+} ions bind to the Ca^{2+} pump, they lose the water molecules that normally surround a Ca^{2+} ion in aqueous solution (see Figure 2-7), but these water molecules are replaced by oxygen atoms with a similar geometry that are part of the transport protein. In contrast, in the E2 state (Figure 11-11a, *right*), several of these binding side chains have moved fractions of a nanometer and are unable to interact with bound Ca^{2+} ions, accounting for the low affinity of the E2 state for Ca^{2+} ions.

FIGURE 11-11 Structure of the catalytic α subunit of the muscle Ca^{2+} ATPase. (a) Ca^{2+}-binding sites in the E1 state (*left*), with two bound calcium ions, and the low-affinity E2 state (*right*), without bound ions. Side chains of key amino acids are white, and the oxygen atoms on the glutamate and aspartate side chains are red. In the high-affinity E1 conformation, Ca^{2+} ions bind at two sites between helices 4, 5, 6, and 8 inside the membrane. One site is formed out of negatively charged oxygen atoms from glutamate and aspartate side chains and from water molecules (not shown), and the other is formed out of side- and main-chain oxygen atoms. Seven oxygen atoms surround the Ca^{2+} ion in both sites. (b) Three-dimensional model of the protein in the E1 state based on the structure determined by x-ray crystallography. There are 10 transmembrane α helices, four of which (purple) contain residues that participate in Ca^{2+} binding. The cytosolic segment forms three domains: the nucleotide-binding domain (N, blue), the phosphorylation domain (P, green), and the actuator domain (A, beige), which connects two of the membrane-spanning helices. (c) Models of the pump in the E1 state (*left*) and in the E2 state (*right*). Note the differences between the E1 and E2 states in the conformations of the N and A domains. Movements of

these domains power the conformational changes of the membrane-spanning α helices (purple) that constitute the Ca^{2+}-binding sites, converting them from a conformation in which the Ca^{2+}-binding sites are accessible from the cytosolic face (E1 state) to one in which the now loosely bound Ca^{2+} ions gain access to the exoplasmic face (E2 state).

[Data from C. Toyoshima and G. Inesi, 2004, *Annu. Rev. Biochem.* **73**:269–292, PDB ID 1su4; and K. Obara et al., 2005, *Proc. Nat'l. Acad. Sci. USA* **102**:14489–14496, PDB ID 1agv.]

The binding of Ca^{2+} ions to the Ca^{2+} pump illustrates a general principle of ion binding to membrane transport proteins that we will encounter repeatedly in this chapter: as ions bind, they lose most of their waters of hydration, but interact with oxygen atoms in the transport protein that have a geometry similar to that of the water oxygen atoms that are bound to them in aqueous solution. This reduces the thermodynamic barrier for ion binding to the protein and allows the ion to bind tightly even from solutions of relatively low concentrations.

The cytosolic region of the Ca^{2+} pump consists of three domains that are well separated from one another in the E1 state (see Figure 11-11b). Each of these domains is connected to the membrane-spanning helices by short segments of amino acids. Movements of these cytosolic domains during the pumping cycle cause movements of the connecting segments, which are transmitted into movements of the attached membrane-spanning α helices. For example, the phosphorylated residue, Asp 351, is located in the phosphorylation (P) domain. The adenosine moiety of ATP binds to the nucleotide-binding (N) domain, but the γ phosphate of ATP

binds to specific residues on the P domain, requiring movements of both the N and P domains. Thus following ATP and Ca^{2+} binding, the γ phosphate of the bound ATP sits adjacent to the aspartate on the P domain that is to receive the phosphate. Although the precise details of these and other protein conformational changes are not yet clear, the movements of the N and P domains are transmitted by lever-like motions of the connecting segments into rearrangements of several membrane-spanning α helices. These changes are especially apparent in the four helices that contain the two Ca^{2+}-binding sites: the changes prevent the bound Ca^{2+} ions from moving back into the cytosol when released, but enable them to dissociate into the exoplasmic space (lumen).

All P-class ATP-powered pumps, regardless of which ion they transport, are phosphorylated on a highly conserved aspartate residue during the transport process. As deduced from cDNA sequences, the catalytic α subunits of all the P-class pumps examined to date have similar amino acid sequences and thus are presumed to have similar arrangements of transmembrane α helices and cytosol-facing A (actuator), P, and N domains (see Figure 11-11). These findings strongly suggest that all such proteins evolved from a common precursor, although they now transport different ions. This suggestion is borne out by the finding that the three-dimensional structures of the membrane-spanning segments of the Na^+/K^+ ATPase and the Ca^{2+} pump are highly similar; the molecular structures of the three cytosolic domains are also very similar. Thus

the operational model in Figure 11-11 is generally applicable to all of the P-class ATP-powered pumps.

The Na^+/K^+ ATPase Maintains the Intracellular Na^+ and K^+ Concentrations in Animal Cells

An important P-class pump that is present in the plasma membranes of all animal cells is the **Na^+/K^+ ATPase**. This ion pump is a tetramer of subunit composition $\alpha_2\beta_2$ and shares structural homology with the Ca^{2+} pump. The small, glycosylated β-transmembrane polypeptide apparently is not involved directly in ion pumping. During its catalytic cycle, the Na^+/K^+ ATPase moves three Na^+ ions *out* of and two K^+ ions *into* the cell per ATP molecule hydrolyzed.

The mechanism of action of the Na^+/K^+ ATPase, outlined in Figure 11-12, is similar to that of the muscle SR calcium pump, except that ions are pumped in *both* directions across the membrane, with each ion moving *against* its concentration gradient. In its E1 conformation, the Na^+/K^+ ATPase has three high-affinity Na^+-binding sites and two low-affinity K^+-binding sites accessible from the cytosolic surface of the protein. The K_d for binding of Na^+ to these cytosolic sites is 0.6 mM, a value considerably lower than the

intracellular Na^+ concentration of $\sim$12 mM; as a result, Na^+ ions normally fully occupy these sites. Conversely, the affinity of the cytosolic K^+-binding sites is low enough that K^+ ions, transported inward through the protein, dissociate from E1 and enter the cytosol despite the high intracellular K^+ concentration. During the E1 $\rightarrow$ E2 transition, the three bound Na^+ ions gain access to the exoplasmic face, and simultaneously, the affinity of the three Na^+-binding sites drops. The three Na^+ ions, now bound to low-affinity Na^+ sites, dissociate one at a time and enter the extracellular medium despite the high extracellular Na^+ concentration. Transition to the E2 conformation also generates two high-affinity K^+ sites accessible from the exoplasmic face. Because the K_d for K^+ binding to these sites (0.2 mM) is lower than the extracellular K^+ concentration (4 mM), these sites will fill with K^+ ions as the Na^+ ions dissociate. Similarly, during the subsequent E2 $\rightarrow$ E1 transition, the two bound K^+ ions are transported inward and then released into the cytosol.

FIGURE 11-12 Operational model of the plasma-membrane Na^+/K^+ ATPase. Only one of the two catalytic α subunits of this P-class pump is depicted. It is not known whether just one or both subunits in a single ATPase molecule transport ions. Ion pumping by the Na^+/K^+ ATPase involves phosphorylation, dephosphorylation, and conformational changes similar to those in the muscle Ca^{2+} ATPase (see Figure 11-11). In this case, hydrolysis of the E2–P intermediate powers the $E2 \rightarrow E1$ conformational change and concomitant transport of two K^+ ions inward. Na^+ ions are indicated by red circles; K^+ ions, by purple squares; high-energy acyl phosphate bond, by $\sim P$; low-energy phosphoester bond, by –P.

Certain drugs (e.g., ouabain and digoxin) bind to the exoplasmic domain of the plasma-membrane Na^+/K^+ ATPase and specifically inhibit its ATPase activity. The resulting disruption in the Na^+/K^+ balance of cells is strong evidence for the critical role of this ion pump in maintaining the normal K^+ and Na^+ ion concentration

gradients. Classic Experiment 11-1 describes the discovery of this important pump, which is required for life.

V-Class H^+ ATPases Maintain the Acidity of Lysosomes and Vacuoles

All V-class ATPases transport only H^+ ions. These proton pumps, present in the membranes of lysosomes, endosomes, and plant vacuoles, function to acidify the lumina of these organelles. The pH of the lysosomal lumen can be measured precisely in live cells by use of particles labeled with a pH-sensitive fluorescent dye. When these particles are added to the extracellular fluid, the cells engulf and internalize them (phagocytosis; see Figure 1-19 and Chapter 17), ultimately transporting them into lysosomes. The lysosomal pH can be calculated from the spectrum of the fluorescence emitted. Alternatively, the DNA encoding a naturally fluorescent protein whose fluorescence depends on the pH can be modified (by adding DNA segments encoding "signal sequences," detailed in Chapters 13 and 14) such that the protein is targeted to the lysosome lumen; fluorescence measurements can then be used to determine the pH in the organelle lumen.

These measurements reveal that a hundredfold or more proton gradient is maintained between the lysosomal lumen (pH ~4.5–5.0) and the cytosol (pH ~7.0). The low lysosomal pH is necessary for

optimal function of the many proteases, nucleases, and other hydrolytic enzymes in the lumen; on the other hand, a cytosolic pH of 5 would disrupt the functions of many proteins optimized to act at pH 7 and lead to death of the cell. Maintenance of the proton gradient depends on a V-class ATPase and thus on ATP production by the cell.

Relatively few protons need to be pumped to acidify an intracellular vesicle. To understand why, recall that a solution of pH 4 has an H^+ ion concentration of 10^{-4} moles per liter, or 10^{-7} moles of H^+ ions per milliliter. There are 6.02×10^{23} atoms of H per mole (Avogadro's number), so a milliliter of a pH 4 solution contains 6.02×10^{16} H^+ ions. Thus at pH 4, a primary spherical lysosome with a volume of 4.18×10^{-15} ml (diameter of $0.2\,\mu m$) would contain just 252 protons. At pH 7, the same organelle would have an average of only 0.2 protons in its lumen, and thus pumping of only about 250 protons would be necessary for lysosome acidification.

By themselves, V-class proton pumps cannot acidify the lumen of an organelle (or the extracellular space) because these pumps are *electrogenic*; that is, a net movement of electric charge occurs during transport. Pumping of just a few protons causes a buildup of positively charged H^+ ions on the exoplasmic (inside) face of the organelle membrane. For each H^+ pumped across, a negative ion (e.g., OH^- or Cl^-) will be left behind on the cytosolic face, causing a buildup of negatively charged ions there. These oppositely charged

ions attract each other on opposite faces of the membrane, generating a charge separation, or electric potential, across the membrane. The lysosome membrane thus functions as a capacitor in an electric circuit, storing opposing charges (anions and cations) on opposite sides of a barrier impermeable to the movement of charged particles.

As more and more protons are pumped and build up excess positive charge on the exoplasmic face, the energy required to move additional protons against this rising electric potential gradient increases dramatically and prevents pumping of additional protons long before a significant transmembrane H^+ concentration gradient is established (Figure 11-13a). In fact, this is the way that P-class proton pumps generate a cytosol-negative potential across plant and yeast plasma membranes.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 11-13 Effect of V-class proton pumps on H^+ concentration gradients and electric potential gradients across cellular membranes. (a) If an intracellular organelle contains only V-class pumps, proton pumping generates an electric potential across the membrane (the cytosolic face becomes negative and the luminal face positive) but no significant change in the intraluminal pH. (b) If the organelle membrane also contains Cl^- channels, anions passively follow the pumped protons, resulting in an accumulation of H^+ and Cl^- ions in the lumen (low luminal pH) but no electric potential across the membrane.

In order for an organelle lumen or an extracellular space (e.g., the lumen of the stomach) to become acidic, movement of protons must be accompanied either by (1) movement of an equal number of anions (e.g., Cl^-) in the same direction or by (2) movement of equal numbers of a different cation in the opposite direction. The first process occurs in lysosomes and plant vacuoles, whose membranes contain V-class H^+ ATPases and anion channels through which accompanying Cl^- ions move (Figure 11-13b). The second process occurs in the lining of the stomach, which contains a P-class H^+/K^+ ATPase that is not electrogenic and pumps one H^+ outward and one K^+ inward. Operation of this pump is discussed later in the chapter.

The V-class proton pumps in lysosomal and vacuolar membranes have been solubilized, purified, and incorporated into liposomes for further study. As shown in Figure 11-14, these pumps consist of two discrete domains: a soluble hydrophilic domain (V_1) on the cytosolic side, and a ringlike transmembrane domain (V_0). V_1 and V_0 are linked by three peripheral stalk structures. The V_1 and V_0 domains each function as rotary motors. ATP hydrolysis by the V_1 domain is coupled to proton translocation through the membrane by means of the rotation of both domains. More specifically, ATP hydrolysis triggers conformational changes that drive the rotation of V_1 by 120° per molecule of ATP hydrolyzed. The rotation of V_1 in turn generates a torque that drives the rotation of the c-subunits against the a subunits in V_0, resulting in proton translocation across the membrane.

FIGURE 11-14 Eukaryotic V-ATPase: rotation of V_0 and V_1 domains drive proton transport across the membrane. (a) The structure of yeast vacuolar V-ATPase as determined by cryo-electron microscopy reveals separate cytosolic V_0 and transmembrane V_1 domains. (b) Cartoon of the pump. (c) *Top:* Cross-sectional view of V_1. The three nucleotide binding sites in V_1 exist in three distinct conformations: tight, with ATP bound; loose, with ADP bound; and open, without any nucleotide bound. Each hydrolysis of ATP triggers a 120° rotation of V_1 relative to V_0. *Bottom:* Rotation of the c subunits in V_0 against the a subunit drives proton translocation from the cytosol to the lumen via a series of protonation and deprotonation of glutamate and aspartate residues.

[Data from J. Zhao et al., 2015, *Nature* **521**:241.]

Recent cryo-electron microscopy structures of the V_0 subunit of a yeast vacuolar V-ATPase has yielded molecular insights into how protons are translocated through the membrane by V_0. These studies revealed the presence of two negatively charged cavities: one gives access to the cytosolic side of the membrane and the other to the luminal side. Positively charged amino acid residues form a barrier in the middle of the membrane that separates the two cavities. Protons enter the cavity on the cytosolic side, and conserved glutamates or aspartates undergo a cycle of protonation and deprotonation as the protons translocate through the pore into the lumen of the vacuole (Figure 11-14b). The rotation of the subunits closes access to the cytoplasm and traps the proton within the pump, and further rotation then releases the protons to the lumen of the vacuole.

ABC Proteins Export a Wide Variety of Drugs and Toxins from the Cell

About 50 different mammalian ABC proteins are now recognized, and mutations in these proteins have been linked to many human diseases (Table 11-3). In eukaryotic cells, ABC proteins localize not only to the plasma membrane but also to the membranes of many intracellular organelles. Several are expressed in abundance in the liver, intestines, and kidneys — sites where natural toxic and waste

products are removed from the body. Substrates for these ABC proteins include sugars, amino acids, cholesterol, bile acids, phospholipids, peptides, proteins, toxins, and foreign substances. The normal function of ABCB1 most likely is to transport various natural and metabolic toxins into the bile or intestinal lumen for excretion or into the urine being formed in the kidney. During the course of its evolution, ABCB1 appears to have acquired the ability to transport drugs whose structures are similar to those of these endogenous toxins. Tumors derived from MDR-expressing cell types, such as hepatomas (liver cancers), are frequently resistant to virtually all chemotherapeutic agents and are thus difficult to treat, presumably because the tumors exhibit increased expression of ABCB1 or a related ABC protein.

TABLE 11-3 • Selected Human ABC Proteins

Protein	Tissue Expression	Function	Disease Caused by Defective Protein
ABCB1 (MDR1)	Many epithelia, blood-brain barrier	Exports glucosylceramides and lipophilic drugs	Inflammatory bowel disease
ABCB4 (MDR2)	Liver	Exports phosphatidylcholine into bile	
ABCB11	Liver	Exports bile salts into bile	Progressive familial intrahepatic cholestasis
CFTR	Exocrine	Transports Cl ions	Cystic fibrosis

	tissue		
ABCDI	Ubiquitous in peroxisomal enzyme	Influences activity of peroxisomal enzyme that oxidizes very long chain fatty acids	Adrenoleukodystrophy (ADL)
ABCG5/8	Liver, intestine	Exports cholesterol and other sterols	β-Sitosterolemia
ABCA1	Ubiquitous	Exports cholesterol and phospholipid for uptake into high-density lipoprotein (HDL)	Tangier's disease
ABCA4	Retina	Transports N-retinyl-phosphatidylethanolamine	Stargardt's disease in photoreceptor cells (juvenile macular degeneration)
ABCA2	Brain, kidney, heart, lung	Exports cholesterol	Alzheimer's disease
ABCA3	Lung	Exports surfactant lipids	Surfactant metabolism dysfunction 3
ABCA12	Lung, skin	Exports lipids	Harlequin ichthyosis
ABCB4	Liver	Exports long-chain phosphatidylcholines	Progressive familial intrahepatic cholestasis 3
ABCC2	Liver, kidney, intestines	Exports bilirubin, bile salts	Dubin-Johnson

ABCD1	Ubiquitous	Exports very long chain fatty acids	Adrenoleukodystrophy
ABCG5	Liver, intestine	Exports cholesterol, plant sterols	Sitosterolemia
ABCG8	Liver, intestine	Exports cholesterol, plant sterols	Sitosterolemia, gallstones

As noted earlier, all members of the very large and diverse ABC superfamily of membrane transport proteins contain two transmembrane (TM) domains and two cytosolic ATP-binding (A) domains (see Figure 11-9). The TM domains, each built of 10 membrane-spanning α helices, form the pathway through which the transported substance (substrate) crosses the membrane (Figure 11-15a) and determine the substrate specificity of each ABC protein. The sequences of the A domains are approximately 30–40 percent homologous in all members of this superfamily, indicating a common evolutionary origin.

FIGURE 11-15 The multidrug transporter ABCB1 (MDR1): Structure and model of ligand export. (a) Cross-sectional view through the center of an ABCB1 protein bound to two molecules of a drug analog, qz59-sss (black), reveals the central location of the ligand-binding site in relation to the phospholipid bilayer: the central ligand-binding cavity is close to the leaflet-leaflet interface of the membrane. During transport, this binding cavity is alternately exposed to the exoplasmic and the cytosolic surface of the membrane. Serines 289 and 290 affect the ligand specificity of the transporter; they are shown as red spheres to highlight their juxtaposition to the bound ligand. Surface residues are colored yellow to denote hydrophobic and blue to denote hydrophilic amino acids. (b)

Three-dimensional structure of ABCB1 with its ligand-binding site facing inward toward the cytosol. In this conformation, a hydrophilic ligand can bind directly from the cytosol. A more hydrophobic ligand can enter into the inner leaflet of the plasma membrane bilayer and then enter the ligand-binding site through a gap in the protein that is accessible directly from the hydrophobic core of the inner leaflet. (c) Model for the structure of ABCB1 with its ligand-binding site facing outward, based on the structures of homologous bacterial ABC proteins. When the protein assumes this conformation, the ligand can either diffuse into the exoplasmic leaflet or directly into the aqueous extracellular medium. (d) Cryo-electron microscopy structure of human ABCG2 in the ADP-bound, inward-facing state, revealing a large cavity facing the cytosol into which the substrate can enter. (e) Mg^{2+} ions, which are important for ATP binding and activity, are shown as light green spheres. ATP (yellow spheres) binding triggers rotation of the α helices, compression of the large cavity, and extrusion of the substrate outside of the cell.

[Data from S. G. Aller et al., 2009, *Science* **323**:1718–1722, PDB ID 3g61; and I. Manolaridis et al., 2018, *Nature* **563**:426–430, PDB ID 6FEQ.]

The first eukaryotic ABC protein to be recognized was discovered during studies on tumor cells and cultured cells that exhibited resistance to several drugs with unrelated chemical structures. Such cells were eventually shown to express elevated levels of a *multidrug-resistance (MDR) transport protein* originally called *MDR1* and now known as *ABCB1*. This protein uses the energy derived from ATP hydrolysis to *export* a large variety of drugs from the cytosol to the extracellular medium. The *Mdr1* gene is frequently amplified in multidrug-resistant cells, resulting in a large overproduction of the ABCB1 protein. In contrast to bacterial ABC proteins, which are built of four discrete subunits, all four domains of mammalian ABCB1 are fused into a single 170-kDa protein.

The substrates of mammalian ABCB1 are primarily planar, lipid-soluble molecules with one or more positive charges; they all compete with one another for transport, which suggests that they bind to the same or overlapping sites on the protein. Many drugs transported out of the cell by ABCB1 have earlier diffused into the cell cytosol from the extracellular medium across the plasma membrane, unaided by transport proteins. Once in the cell, they block various cellular functions. Two such drugs, used to treat certain cancers, are colchicine and vinblastine, which block assembly of microtubules (see Chapter 18). ATP-powered export of such drugs by MDR1 reduces their concentration in the cytosol. As a result, a much higher extracellular drug concentration is required to kill cells that express ABCB1 than those that do not. That ABCB1 is an ATP-powered small-molecule pump has been demonstrated with liposomes containing the purified protein. Different drugs enhance the ATPase activity of these liposomes in a dose-dependent manner corresponding to their ability to be transported by ABCB1.

The three-dimensional structure of ABCB1, together with those of homologous bacterial and eukaryotic ABC proteins, revealed the protein's mechanism of transport as well as the key to its ability to bind and transport a wide array of hydrophilic and hydrophobic substrates (see Figure 11-15). The two TM domains form a binding site in the center of the membrane that alternates between an inward-facing (Figure 11-15b) and an outward-facing (Figure 11-15c) orientation, conforming to the alternating access model. The alternation between these two conformational states is powered by

ATP binding to the two A subunits and its subsequent hydrolysis to ADP and P_i.

The substrate-binding cavity formed by ABCB1 is large. Some of the amino acids that line the cavity — mainly tyrosine and phenylalanine — have aromatic side chains, allowing ABCB1 to bind multiple types of hydrophobic ligands. Other segments of the cavity are lined with hydrophilic residues, allowing hydrophilic or amphipathic molecules to bind. In the inward-facing conformation, the binding site is open directly to the surrounding aqueous solution, allowing hydrophilic molecules to enter the binding site directly from the cytosol. In addition, a gap in the protein is accessible directly from the hydrophobic core of the inner leaflet of the membrane bilayer; through this gap hydrophobic molecules can enter the binding site directly from the inner leaflet (see Figure 11-15b). After the ATP-powered change to the outward-facing conformation, molecules can exit the binding site into the outer membrane leaflet or directly into the extracellular medium (see Figure 11-15c).

The human ABCG2 structure has recently been determined in substrate- and ATP-bound states. This structure provided additional insights into the mechanisms underlying ATP-driven substrate translocation (Figure 11-15d, e). ABCG2 is also known as the Breast Cancer Resistance Protein and its expression levels are correlated with a poor outcome in breast as well as other cancers. A clever

experimental strategy made use of a mutant form of ABCG2 that exhibits decreased rates of transport and of ATP hydrolysis. High-resolution cryo-electron microscopy was used to capture the transporter bound to the substrate in the internal facing, pre-translocation state and bound to ATP in the post-translocation state. These studies revealed a large substrate-binding cavity in the internal-facing state, with a plug creating a smaller cavity toward the external-facing part of the protein. ATP binding triggered rotation of the α helices of the A domains, compressing the substrate-binding cavity and extruding the substrate through the plug to the external cavity, with release of the substrate to the outside. While not clear, ATP hydrolysis may be required to return the protein transporter to the inward-facing state.

Certain ABC Proteins "Flip" Phospholipids and Other Lipid-Soluble Substrates from One Membrane Leaflet to the Other

As shown in Figure 11-15, ABCB1 and ABCG2 can move, or "flip," a hydrophobic or amphipathic substrate molecule from the inner leaflet of the membrane to the outer leaflet. This otherwise energetically unfavorable reaction is powered by the ATPase activity of the protein, and is required for maintaining the asymmetric distribution of phospholipids across the cytoplasmic and exoplasmic

membrane leaflets (Chapter 10) and for transporting lipids across cellular membrane. Support for this so-called **flippase** model of transport by ABCB1 comes from experiments on ABCB4 (originally called *MDR2*), a protein homologous to ABCB1 that is present in liver cells in the region of the plasma membrane that faces the thin tubes (canaliculi) that collect bile. ABCB4 moves phosphatidylcholine from the cytosolic to the exoplasmic leaflet of the plasma membrane for subsequent release into the bile in combination with cholesterol and bile acids, which themselves are transported by other ABC superfamily members. Still other ABC superfamily members are also flippases that export various lipids from cells, presumably by mechanisms similar to that of ABCB1 (see Table 11-3).

The flipping of lipids across membranes is required for the generation of glycoproteins within the endoplasmic reticulum in eukaryotic cells or the periplasm of prokaryotes (see Chapter 13). This process provides a way to get the hydrophilic oligosaccharides needed to form glycoproteins across the hydrophobic membrane. In this process, oligosaccharides are added to the cytosolic side of long polyisoprenol membrane lipids to form lipid-linked oligosaccharides (LLOs). These LLOs are then flipped across the membrane into the endoplasmic reticulum (or into the periplasm in prokaryotes) so that the oligosaccharides can be transferred to membrane and secreted proteins to generate glycoproteins. Recent x-ray crystal structures of a dimeric ABC transporter from

Campylobacter jejuni (a bacteria that commonly causes food poisoning) that mediates flipping of LLOs across the membrane captured the transporter in inward- and outward-facing states. These structures revealed a novel lipid-flipping mechanism (Figure 11-16d). Initially, the lipid tail of a lipid-linked oligosaccharide (LLO) binds the extracellular-facing helix of one of the flippase subunits (step **1**). Its binding promotes exchange of ATP for ADP, triggering the dimer to convert to an outward-open state (step **2**) that allows the hydrophilic oligosaccharide head of the LLO to enter the positively charged pore of the transporter (step **3**). ATP hydrolysis drives the return of the dimer to an inward-open conformation, squeezing the LLO head to the outward side of the membrane (step **4**). The LLO lipid tail then dissociates from the flippase and extends into the cytosolic side of the membrane. In this mechanism, the transporter protects the hydrophilic oligosaccharide head of the LLO from the hydrophobic milieu of the membrane, allowing the lipid tails to flip from one side of the membrane to the other.

FIGURE 11-16 An ABC transporter from *Campylobacter jejuni* flips lipid-linked oligosaccharides across the membrane. (a) The inward-facing structure of the PglK ABC transporter, with a larger cavity facing the cytosol. Subunits are shown in peach and purple, with the extracellular-facing helix (EH) labeled. (b) The ADP-bound, outward-facing structure in which the cytosolic cavity is occluded. (c) The conversion of inward- to outward-facing states is associated with conformational changes. (d) In the proposed model for the flippase mechanism, the PglK subunits are shown as cartoon-like structures in peach and purple, with the EH labeled. The lipid tail of the LLO is yellow and the oligosaccharide head light purple. The lipid tail interacts with the EH (step 1 – 2); ATP replaces ADP, which opens the cytosolic cavity (step 2), into which the large oligosaccharide head of the LLO enters (step

3); ATP hydrolysis triggers conformational changes that achieve occlusion of the cytosolic cavity, dislodging and ejecting the oligosaccharide head into the periplasm (step 4) and flipping the direction of the lipid tail within the membrane.

The ABC Cystic Fibrosis Transmembrane Regulator Is a Chloride Channel, Not a Pump

Several human genetic diseases are associated with defective ABC proteins (see Table 11-3). The most common (1 in 2500 births) is cystic fibrosis (CF), caused by a mutation in the gene encoding the *cystic fibrosis transmembrane regulator* (*CFTR*, also called *ABCC7*). Like other ABC proteins, CFTR has two transmembrane TM domains and two cytosolic ATP-binding domains (A domains). CFTR contains an additional R (regulatory) domain on the cytosolic face; R links the two homologous halves of the protein, creating an overall domain organization of TM1–A1–R–TM2–A2. CFTR is a Cl^- channel that opens upon phosphorylation and ATP binding to allow Cl^- anions to flow down their electrochemical gradient. It is expressed in the apical plasma membranes of epithelial cells in the lungs, sweat glands, pancreas, and other tissues, and mutations in the protein decrease the capacity of these membranes to transport Cl^-. For instance, CFTR protein is important for reuptake into the cells of sweat glands of Cl^- lost by sweating; babies with cystic fibrosis, if

licked, often taste salty because this reuptake is inhibited. Over time, as a result of disrupted salt and water homeostasis, patients with cystic fibrosis accumulate dehydrated mucus in their lungs and other tissues, leading to chronic respiratory infections and digestive system disorders, which can ultimately result in organ failure.

Until recently, our understanding of CFTR channel structure and function was derived from biochemical and biophysical studies, along with x-ray crystal structures of fragments of the CFTR protein. In 2017, however, the high-resolution structures of the full-length zebrafish and human CFTR channels were solved using cryo-electron microscopy (Figure 11-17). While it was known that the channel was gated by phosphorylation and ATP binding, comparison of the structure of open and closed CFTR channels revealed the major conformational changes produced by phosphorylation and ATP binding to open the channel. These structures show that channel gating is regulated by two processes: phosphorylation of the cytosolic R domain by cAMP-dependent protein kinase (PKA, discussed in Chapter 15), followed by binding of ATP to the cytosolic A domains. In the unphosphorylated state, the R domain is wedged between transmembrane α helices, keeping the A1 and A2 domains apart and blocking the anion channel. Phosphorylation by PKA triggers a conformational change that moves the R domain away from the A1 and A2 interface, and, following ATP binding, the two A domains dimerize, narrowing (but not closing) the opening of the channel on the cytosolic side and widening it on the extracellular side of the membrane, allowing the

anions to flow through the channel. The ion channel pathway is lined with positively charged amino acids, making the channel specific for conductance of anions.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 11-17 Structure and function of the cystic fibrosis transmembrane regulator (CFTR). (a) Ribbon structures of the human CFTR in the dephosphorylated, ATP-free state on the left and in the phosphorylated, ATP-bound state on the right. The unresolved regions of the structure are shown as thin red lines, and unstructured regions within the R domain are shown in pink.

Phosphorylation of the R domain moves it out of the ATP-binding region and allows ATP binding and dimerization of the two ATP-binding (A) domains. This narrows the opening on the cytosolic side, with a widening of the pore on the extracellular side of the membrane. (b) A cartoon of the CFTR, with each subunit of the dimer shown in purple and peach. In the unphosphorylated, ATP-free state, the R-domain (shown as a red line) is wedged between the two subunits. Phosphorylation of R moves it out of the region between the two subunits, ATP binds and the two ATP-binding (A) sites dimerize. Dimerization narrows the channel on the cytosolic face and opens the channel on the extracellular face so that the chloride ions can travel through the pore (lined with positively charged amino acid residues) down its electrochemical gradient.

[Data from Z. Zhang et al., 2017, *Cell* **170**:483; and Z. Zhang et al., 2018, *Proc. Nat'l Acad. Sci. USA* **115**:12757.]

About two-thirds of all CF cases can be attributed to a single mutation in CFTR: deletion of Phe 508 (F508del) in the ATP-binding A1 domain. At body temperature, the mutant protein fails to fold properly and to move to the cell surface, where it normally functions. Interestingly, if cells expressing the mutant protein are incubated at room temperature, the protein folds and accumulates normally on the plasma membrane, where it functions nearly as well as the wild-type CFTR channel. Recently, a series of small molecules have been chemically synthesized that bind to this mutant CFTR protein in CF patients and stabilize the folded form at 37 °C, allowing it to traffic normally to the cell surface and partially reverse the effects of the disease. These molecules are known as *CFTR correctors*. They only promote the cell surface trafficking of a fraction of CFTR channels and thus only partially reverse the effects

of the disease. Another CFTR mutation, Gly 551 to Asp (G551D), accounts for approximately 5 percent of CF cases and results in a channel that folds normally and accumulates normally on the plasma membrane but is defective in Cl^- transport because the mutation disrupts ATP binding. In 2012, a small molecule drug called *Ivacaftor*, which increases the flow of Cl^- ions through the mutant channel, was approved by the U.S. Food and Drug Administration (FDA) to treat CF patients whose disease is caused by this mutation. This drug, known as a *CFTR potentiator*, represents one of the first successful personalized therapies resulting from a molecular understanding of the disease-causing protein. Recently, the FDA has approved treatment of F508del cystic fibrosis patients with a combination of CFTR correctors and the CFTR potentiator Ivacaftor, which increases the flow of Cl^- ions through those channels that do reach the plasma membrane. This drug combination exemplifies the use of targeted combination drug therapies resulting from detailed molecular understanding of how specific mutations cause disease. ■

KEY CONCEPTS OF SECTION 11.3

ATP-Powered Pumps and the Intracellular Ionic Environment

- Four classes of transmembrane proteins couple the energy-releasing hydrolysis of ATP with the energy-requiring transport of substances against their concentration gradients: P-, V-, and F-class pumps and ABC proteins (see Figure 11-9).
- The combined action of P-class Na^+/K^+ ATPases in the plasma membrane and homologous Ca^{2+} ATPases in the plasma membrane or SR creates the usual ionic

milieu of animal cells: high K^+, low Ca^{2+}, and low Na^+ in the cytosol; low K^+, high Ca^{2+}, and high Na^+ in the extracellular fluid.

- In P-class pumps, phosphorylation of the α (catalytic) subunit and changes in conformational states are essential for coupling ATP hydrolysis to transport of H^+, Na^+, K^+, or Ca^{2+} ions (see Figures 11-10 through 11-13).
- V- and F-class ATPases, which transport protons exclusively, are large, multisubunit complexes with a proton-conducting channel in the transmembrane domain and ATP-binding sites in the cytosolic domain.
- V-class proton pumps in animal lysosomal and endosomal membranes and plant vacuolar membranes are responsible for maintaining a lower pH inside the organelles than in the surrounding cytosol (see Figure 11-14).
- V- and F-class ATPases transport protons across the membrane using a rotary motor mechanism.
- All members of the large and diverse ABC superfamily of membrane transport proteins contain four core domains: two transmembrane domains, which form a pathway for solute movement and determine substrate specificity, and two cytosolic ATP-binding domains (see Figure 11-15).
- The two T domains of the multidrug transporter ABCB1 form a ligand-binding site in the middle of the plane of the membrane; ligands can bind directly from the cytosol or from the inner-membrane leaflet through a gap in the protein.
- The ABC superfamily includes about 50 mammalian proteins (e.g., ABCB1, ABCA1) that transport a wide array of substrates, including toxins, drugs, phospholipids, peptides, and proteins, into or out of the cell.
- Biochemical experiments directly demonstrate that ABCB4 (MDR2) possesses phospholipid flippase activity (see Figure 11-16).
- High resolution cryo-electron microscopy of a flippase from *Campylobacter jejuni* reveals a novel mechanism by which an ABC transporter flips a lipid-linked oligosaccharide across the membrane.
- CFTR, an ABC protein, is a Cl^- channel, not a pump. Channel opening is triggered by protein phosphorylation and by binding of ATP to the two A domains (see Figure 11-17).
- Mutations in CFTR cause cystic fibrosis; small molecules targeting these mutations, classified as CFTR correctors and CFTR potentiators, are used to treat cystic fibrosis patients.

11.4 Nongated Ion Channels and the Resting Membrane Potential

We have just seen that ATP-powered ion pumps transport ions *against* their concentration gradients. In addition, the plasma membrane contains channel proteins that allow the principal cellular ions (Na^+, K^+, Ca^{2+}, and Cl^-) to move through them *down* their concentration gradients. Ion pumps and channels work together to generate a difference in voltage, or electric potential, across the plasma membrane. ATP-powered ion pumps generate differences in ion concentrations across the plasma membrane, and ions move selectively through ion channels down these concentration gradients (see Figure 11-3). All channel proteins have transmembrane domains that create a hydrophilic passage or pore for ions to travel through in order to cross the membrane. The size of the pore and the composition of the amino acids that line the pore determine which ions are transported through the channel. By allowing the passage of selective ions across the membrane, channels function to generate a tightly controlled electric potential across the membrane.

In all cells, the magnitude of this electric potential is generally between 60 and 90 millivolts (mV), with the *inside* cytosolic face of the plasma membrane always *negative* with respect to the outside exoplasmic face. This value does not seem like much until we

consider that the thickness of the plasma membrane is only $\sim 3.5\,\mathrm{nm}$. Thus the voltage gradient across the plasma membrane is 0.07 V per 3.5×10^{-7} cm, or 200,000 volts per centimeter! (To appreciate what this means, consider that high-voltage transmission lines for electricity use gradients of about 200,000 volts per kilometer, 10^5-fold less!)

The ionic gradients and electric potential across the plasma membrane play crucial roles in many biological processes. As noted previously, and as described more fully in Chapter 15, a rise in the cytosolic Ca^{2+} concentration is an important regulatory signal, initiating contraction in muscle cells and triggering in many cells secretion of proteins, such as digestive enzymes from pancreatic cells. In many animal cells, the combined force of the Na^+ concentration gradient and the membrane electric potential drives the uptake of amino acids and other molecules against their concentration gradients by symporters and antiporters (see Figure 11-3 and Section 11.5). Furthermore, electrical signaling by neurons depends on the opening and closing of ion channels in response to changes in the membrane electric potential (see Chapter 23).

Here we discuss the origin of the membrane electric potential in resting non-neuronal cells (often called the cell's **resting membrane potential**). We also examine how ion channels mediate the selective movement of ions across a membrane and consider useful experimental techniques for characterizing the functional

properties of channel proteins. We address the role of ion channels in electrical signaling in neuronal cells in Chapter 23.

Selective Movement of Ions Creates a Transmembrane Electric Gradient

To help explain how an electric potential across the plasma membrane can arise, we first consider a set of simplified experimental systems in which a membrane separates a 15 mM NaCl/150 mM KCl solution in the cytosol (Figure 11-18a, *left*) from a 150 mM NaCl/15 mM KCl solution in the extracellular fluid (Figure 11-18a, *right*). A potentiometer (voltmeter) is connected to both solutions to measure any electric potential across the membrane. Initially, both solutions contain an equal number of positive and negative ions. If the membrane is impermeable to all ions, no ions will flow across it. Furthermore, there will be no difference in voltage, or electric potential gradient, across the membrane, as shown in Figure 11-18a.

EXPERIMENTAL FIGURE 11-18 Generation of a transmembrane electric potential (voltage) depends on the selective movement of ions across a semipermeable membrane. In this experimental system, a membrane separates a 15 mM NaCl/150 mM KCl solution in the cytosol (*left*) from a 150 mM NaCl/15 mM KCl solution in the extracellular fluid (*right*); these ion concentrations are similar to those in cytosol and blood, respectively. If the membrane separating the two solutions is impermeable to all ions (a), no ions can move across the membrane, and no electric potential is registered on the potentiometer connecting the two solutions. If the membrane is

selectively permeable only to K^+ (b) or only to Na^+ (c), then diffusion of these ions through their respective channels leads to a separation of charge across the membrane. At equilibrium, the membrane potential caused by the charge separation becomes equal to the Nernst potential E_K or E_{Na} registered on the potentiometer. In (b) and (c), the K^+ and Na^+ cations are denoted by the pink plus signs and the Cl^- anions are denoted by the light blue minus signs. See the text for further explanation.

Now suppose that the membrane contains K^+ channels that accommodate K^+ ions but exclude Na^+ and Cl^- ions (Figure 11-18b). K^+ ions then tend to move down their concentration gradient from the cytosol (*left*) to the extracellular fluid (*right*), leaving an excess of negative Cl^- ions (light blue) compared with K^+ ions (pink) on the cytosolic (*left*) side and generating an excess of positive K^+ ions compared with Cl^- ions on the extracellular (*right*) side. The excess K^+ in the extracellular (*right*) side and Cl^- on the cytosolic (*left*) side remain near the respective surfaces of the membrane because the excess positive charges on one side of the membrane are attracted to the excess negative charges on the other side. The resulting separation of charge across the membrane constitutes an electric potential, or voltage, and the cytosolic (*left*) side of the membrane has excess positive charge with respect to the extracellular (*right*) side.

As more and more K^+ ions move through channels across the membrane, the magnitude of this charge difference (i.e., voltage) increases. However, continued cytosol (*left*) to extracellular (*right*)

movement of the K^+ ions is eventually inhibited by the mutual repulsion between the excess positive (K^+) charges accumulated on the extracellular (*right*) side of the membrane and by the attraction of K^+ ions to the excess negative charges built up on the cytosolic (*left*) side. The system soon reaches an equilibrium point at which the two opposing factors that determine the movement of K^+ ions — the membrane electric potential and the ion concentration gradient — balance each other out. At equilibrium, there is no net movement of K^+ ions across the membrane. Thus this membrane, like all cellular membranes, acts as a *capacitor* — a device consisting of a thin sheet of nonconducting material (the hydrophobic interior) surrounded on both sides by electrically conducting material (the polar phospholipid head groups and the ions in the surrounding aqueous solution) that can store positive charges on one side and negative charges on the other.

If a membrane is permeable only to K^+ ions, then at equilibrium, the measured electric potential across the membrane equals the potassium equilibrium potential in volts, E_{K}. The magnitude of E_{K} is given by the *Nernst equation,* which is derived from basic principles of physical chemistry:

$$E_{\mathrm{Na}} = \frac{RT}{ZF} \ln \frac{[\mathrm{K}_{\mathrm{right}}]}{[\mathrm{K}_{\mathrm{left}}]} \tag{11-2}$$

where R (the gas constant) = 8.28 joules/(degree · mol); T (the absolute temperature in degrees Kelvin) = 293 °K at 20 °C; Z (the charge, also called the *valence*) is here equal to $+1$; F (the Faraday constant) = 96,500 coulombs/(mol · V); and $[\mathrm{K}_{\mathrm{left}}]$ and $[\mathrm{K}_{\mathrm{right}}]$ are the Ka^{+} concentrations on the left and right sides, respectively, at equilibrium. By convention, the potential is expressed as the *cytosolic* face of the membrane relative to the *exoplasmic* face, and the equation is written with the ion concentration of the extracellular solution (here the right side of the membrane) placed in the numerator and that of the cytosol in the denominator.

At 20 °C (room temperature), Equation 11-2 reduces to

$$E_{\mathrm{K}} = 0.059 \log_{10} \frac{[\mathrm{K}_{\mathrm{right}}]}{[\mathrm{K}_{\mathrm{left}}]} \tag{11-3}$$

If $[\mathrm{K}_{\mathrm{right}}]/[\mathrm{K}_{\mathrm{left}}] = 1/10$, a tenfold ratio of concentrations as in Figure 11-18b, then $E_{\mathrm{K}} = -0.059\,\mathrm{V}$ (or $-59\,\mathrm{mV}$), with the left, cytosolic side negative with respect to the right, exoplasmic side.

If the membrane is permeable only to Na^{+} ions and not to K^{+} or Cl^{-} ions, then a similar equation describes the sodium equilibrium potential E_{Na}:

$$E_{\mathrm{Na}} = 0.059 \log_{10} \frac{[\mathrm{Na}_{\mathrm{right}}]}{[\mathrm{Na}_{\mathrm{left}}]}$$

(11-4)

The *magnitude* of the membrane electric potential is the same (59 mV, for a tenfold difference in ion concentrations), but the cytosolic (left) side is now *positive* with respect to the extracellular (right) side (Figure 11-18c), so the polarity is opposite to that obtained across a membrane selectively permeable to K^+ ions.

The Resting Membrane Potential in Animal Cells Depends Largely on the Outward Flow of K^+ Ions Through Open K^+ Channels

The plasma membranes of animal cells contain many open K^+ channels but few open Na^+, Cl^-, or Ca^{2+} channels. As a result, the major ionic movement across the plasma membrane is the movement of K^+ from the *inside outward*, powered by the K^+ concentration gradient. This movement leaves an excess of *negative* charge on the cytosolic face of the plasma membrane and creates an excess of *positive* charge on the exoplasmic face, as in the experimental system shown in Figure 11-18b. This outward flow of K^+ ions is the major determinant of the inside-negative membrane potential. The channels through which the K^+ ions flow, called **resting K^+ channels**, alternate, like all channels, between an open

and a closed state (see Figure 11-2), but since their opening and closing is not affected by the membrane potential or by small signaling molecules, these channels are referred to as *nongated*. In contrast, the various gated channels in neurons and other excitable cells (see Chapter 23) open only in response to specific ligands or to changes in membrane potential.

Quantitatively, the usual resting membrane potential of approximately –60 mV is relatively close to the potassium equilibrium potential, calculated from the Nernst equation and the K^+ concentrations in cells and surrounding media (see Table 11-2; also note that the resting membrane potential can vary in different cell types from –60 to –90 mV). Usually the resting membrane potential is slightly lower (less negative) than that calculated from the Nernst equation because of the presence of a few open Na^+ channels. These channels allow the net *inward* flow of Na^+ ions, making the cytosolic face of the plasma membrane more positive — that is, less negative — than predicted by the Nernst equation for K^+.

The K^+ ion would not flow inward at all if it were not for the presence of the K^+ concentration gradient. The concentration gradient that drives the flow of ions through resting K^+ channels is generated by the Na^+/K^+ ATPase described previously (see Figures 11-3 and 11-12). In the absence of this pump, or when it is inhibited,

the K^+ concentration gradient cannot be maintained, the membrane potential falls to zero, and the cell eventually dies.

Although resting K^+ channels play the dominant role in generating the electric potential across the plasma membranes of animal cells, this is not the case in bacterial, plant, and fungal cells. The inside-negative membrane potential in plant and fungal cells is generated by transport of positively charged protons (H^+) out of the cell by ATP-powered proton pumps, a process similar to what occurs in lysosomal membranes lacking Cl^- channels (see Figure 11-13a): each H^+ pumped out of the cell leaves behind a Cl^- ion, generating an inside-negative electric potential across the membrane. In aerobic bacterial cells, an inside-negative potential is generated by outward pumping of protons during electron transport, a process similar to proton pumping in mitochondrial inner membranes that will be discussed in detail in Chapter 12 (see Figure 12-19).

The electric potential across the plasma membrane of a cell can be measured with a microelectrode inserted into the cell and a reference electrode placed in the extracellular fluid. The two electrodes are connected to a potentiometer capable of measuring small potential differences (Figure 11-19). The potential across the plasma membrane of most animal cells generally does not vary with time. In contrast, neurons and muscle cells — the principal types of electrically active cells — undergo controlled changes in their membrane potential, as we discuss in Chapter 23.

EXPERIMENTAL FIGURE 11-19 The electric potential across the plasma membrane of a live cell can be measured. A microelectrode, constructed by filling a glass tube of extremely small diameter with a conducting fluid such as a KCl solution, is inserted into a cell in such a way that the plasma membrane seals itself around the tip of the electrode. A reference electrode is placed in the extracellular medium. A potentiometer connecting the two electrodes registers the potential — in this case, –60 mV, with the cytosolic face *negative* with respect to the exoplasmic face of the membrane. A potential difference is registered only when the microelectrode is inserted into the cell; no potential is registered if the microelectrode is in the extracellular fluid.

Ion Channels Are Selective for Certain Ions by Virtue of a Molecular Selectivity Filter

All ion channels exhibit specificity for particular ions: K^+ channels allow K^+ ions, but not closely related Na^+ ions, to enter them, whereas Na^+ channels admit Na^+, but not K^+. K^+ channels can be divided into four classes on the basis of their structure and function: the tandem-pore domain K^+ channels (constitutively open, e.g., the resting K^+ channel); ligand-activated K^+ channels; inwardly rectifying K^+ channels (transport positive K^+ ions more easily in the inward direction, into the cell), and voltage-gated K^+ channels (which we discuss in Chapter 23 in the context of their role in electrical signaling in neurons). All K^+ channels possess transmembrane helices that span the lipid bilayer, and all K^+ channels can be divided into a pore-forming domain and a regulatory domain. K^+ ions are transported through the pore-forming domain, whereas the regulatory domain opens or closes the pore in response to distinct stimuli. The regulatory domain differs between classes, but the pore-forming domain is similar in all K^+ channels.

Determination of the three-dimensional structure of a bacterial K^+ channel first revealed how the exquisite ion selectivity of K^+ channels is achieved, using a mechanism that has been shown to be conserved in the many bacterial and eukaryotic K^+ channel structures that have been solved in recent years. The similarity of the structural features that are used to generate ion selectivity suggest that all K^+ channels derived from a single type of channel protein.

Like all other K^+ channels, bacterial K^+ channels are built of four identical transmembrane subunits symmetrically arranged around a central pore (Figure 11-20a, b). Each subunit contains two membrane-spanning α helices and a short P (pore) segment that partly penetrates the membrane bilayer from the exoplasmic surface. In the tetrameric K^+ channel, the eight transmembrane α helices (two from each subunit) form an inverted cone, generating a water-filled cavity called the *vestibule* in the central portion of the channel that extends halfway through the membrane toward the cytosolic side. Four extended loops that are part of the four P segments form the actual *selectivity filter* in the narrow part of the pore near the exoplasmic surface, above the vestibule.

FIGURE 11-20 Structure of a resting K^+ channel from the bacterium *Streptomyces lividans.* All K^+ channels are tetramers comprising four identical subunits, each containing two conserved membrane-spanning α helices, and a shorter P, or pore, segment. The gated K^+ channels have additional α helices and are described in Chapter 23. (a) Side view of the KcsA K^+ channel, with each monomer consisting of two transmembrane α helices and a pore that is selective for K^+ ions (purple spheres). (b) Top view of the channel, revealing its fourfold symmetry, with a K^+ ion in the pore. (c) Electronic density map of two diagonal subunits, showing the orientation of the carbonyl oxygen atoms (red) in coordinating the K^+ ions. (d) Four conserved Thr-Val-Gly-Tyr-Gly residues form the selectivity filter, with dehydrated K^+ ions stabilized by the negatively charged carbonyl groups so that they can translocate through the pore in single file. (e) The K^+ ions are in two conformations, either in S2 and S4, or in S1 and S3 during translocation, with water molecules (red spheres) in the vacant positions.

[Data from Y. Zhou et al., 2001, *Nature* **414**:43, PDB ID 1k4c; D. Naranjo, 2016, *J. Gen. Physiol.* **148**:277; and Q. Kuang et al., 2015, *Cell. Mol. Life Sci.* **72**:3677.]

Several related pieces of evidence support the role of P segments in ion selection. First, the amino acid sequences of the P segments in all known K^+ channels are highly homologous and are different from those in other ion channels. Second, mutations of certain amino acids in this segment alter the ability of a K^+ channel to distinguish Na^+ from K^+. Finally, replacing the P segment of a bacterial K^+ channel with the homologous segment from a mammalian K^+ channel yields a chimeric protein that exhibits normal selectivity for K^+ over other ions. Thus all K^+ channels are thought to use the same mechanism to distinguish K^+ from other ions.

The selectivity filter in K^+ channels is able to select K^+ over Na^+ due mainly to the backbone carbonyl oxygen atoms on residues located in a Thr-Val-Gly-Tyr-Gly sequence that is found in an analogous position in the P segment in every known K^+ channel (note that in some channels, the Tyr residue is a Phe). As a K^+ ion enters the selectivity filter, it passes into the narrow space between the filter sequences of the four P-segments contributed by the four adjacent subunits. There the K^+ ion loses its eight waters of hydration, but is bound in the same geometry to eight backbone carbonyl oxygen atoms of the Thr-Val-Gly-Tyr-Gly sequence, two from the extended loop in each of the four P segments lining the channel (Figure 11-20c, d). These carbonyl oxygen atoms form four

evenly spaced K^+ ion binding sites which can bind to four K^+ ions. These protein oxygen atoms mimic the oxygen in water, and as such, the activation energy required for passage of K^+ ions into the channel from an aqueous solution is low.

The ease of passage into the channel in turn raises the question of how K^+ ions are released from their binding sites in the P-segment to allow rapid transport. Analysis of ion occupancy revealed that only two K^+ ions are present in the P segment at a time, either in the S1 and S3 conformation, or in the S2 and S4 conformation (Figure 11-20e), with two water molecules occupying the other, vacant sites. The finding that K^+ ions move through the channel at near the diffusion limit suggests that the binding of K^+ to the sites in P segment is weak, with repulsion of the two K^+ ions in the P segment promoting their transport through the pore.

Na^+ ions are smaller than K^+ ions. How, then, can a channel protein exclude smaller Na^+, yet allow passage of larger K^+? The answer to this question is simple and elegant. A dehydrated Na^+ ion is too small to bind to all eight carbonyl oxygen atoms that line the selectivity filter with the same geometry as a Na^+ ion surrounded by its normal eight water molecules in aqueous solution. As a result, Na^+ ions "prefer" to remain in water rather than enter the selectivity filter, and thus the change in free energy for entry of Na^+ ions into the channel is relatively high (Figure 11-21a, *right*). This difference in free energies favors passage of K^+ ions through the

channel over Na^+ ions by a factor of 1000. Like Na^+, the dehydrated Ca^{2+} ion is smaller than the dehydrated K^+ ion and cannot interact properly with the oxygen atoms in the selectivity filter. Furthermore, because a Ca^{2+} ion has two positive charges and binds water oxygen atoms more tightly than does a single positive Na^+ or K^+ ion, more energy is required to strip the waters of hydration from Ca^{2+} than from K^+ or Na^+.

FIGURE 11-21 Mechanism of ion selectivity and transport in resting K^+ channels. (a) Schematic diagrams of K^+ and Na^+ ions hydrated in solution

and in the pore of a K^+ channel. As K^+ ions pass through the selectivity filter, they lose their bound water molecules and become bound instead to eight backbone carbonyl oxygen atoms (four of which are shown) that are part of the conserved amino acid sequence in the channel-lining selectivity filter loop of each P segment. The smaller Na^+ ions, with their tighter shell of water molecules, cannot perfectly bind to the channel oxygen atoms and therefore pass through the channel only rarely. (b) Overlay of the selectivity filters in the KcsA K^+ channel (pink) and the NavAb Na^+ channel (yellow). The selectivity pore in the NavAb Na^+ channel is wider and shorter than the selectivity filter in the KcsA K^+ channel. See C. Armstrong, 1998, *Science* **280**:56.

[Data from R. F. Stephens et al., 2015, *Front. Physiol.* **6**:153.]

The first three-dimensional crystal structure of a bacterial voltage-gated Na^+ channel was determined in late 2011. This structure showed that the channel contains an ion selectivity filter that is slightly larger than the filter in K^+ channels, and that it transports hydrated rather than dehydrated Na^+ ions (Figure 11-21b). The structures of multiple eukaryotic voltage-gated Na^+ channels have been solved in recent years. We will examine these structures and their function in electrical signaling in neurons in more detail in Chapter 23.

Patch Clamps Permit Measurement of Ion Movements Through Single Channels

Once it was realized that there are only one or a few ion channels per square micrometer of plasma membrane in most cells, it became possible to record ion movements through single ion channels, using a technique known as **patch clamping**. This technique measures the rates at which these channels open and close and conduct specific ions. As illustrated in Figure 11-22a and b, a tiny glass pipette is tightly sealed, using suction, to the surface of a cell; the segment of the plasma membrane within the tip of the pipette will contain only one or a few ion channels. The only current that crosses through the patch of membrane must pass through these channels as ions flow. An electrical recording device detects this ion flow, measured as electric current, through the channels; this ion flow usually occurs in small bursts when a channel is open (Figure 11-22c). The electrical device also "clamps" or locks the electric potential across the membrane at a predetermined value (hence the term *patch clamping*). The inward or outward movement of ions across a patch of membrane is quantified from the amount of electric current needed to maintain the membrane potential at a particular clamped value (see Figure 11-22a).

EXPERIMENTAL FIGURE 11-22 Current flow through individual ion channels can be measured by patch clamping. (a) Basic experimental arrangement for measuring current flow through individual ion channels in the plasma membrane of a live cell. The patch electrode, filled with a current-conducting saline solution, is applied, with a slight suction, to the plasma membrane. The 0.5-μm-diameter tip covers a region that contains only one or a few ion channels. A recording device measures current flow only through the channel or channels in that region. (b) Photomicrograph of the cell body of a cultured neuron and the tip of a patch pipette touching the plasma membrane. (c) Current traces from patch-clamp experiments measuring activity of a single voltage-gated K^+ channel. Patches of membrane containing a voltage-gated K^+ channel were clamped at a negative membrane potential and voltage steps were applied while measuring the changes in current. The top row shows the voltage applied to the membrane; first the membrane is held at a negative

potential and then voltage steps are applied to hold ("clamp") the membrane potential at 0 mV (A) or $+50$ mV (B). The voltage traces below show K^+ channel opening by an increase in the current trace and the channel closing by the rapid decrease in the current trace. The amplitude of the current trace is greater and the channel opening is quicker when the membrane is more depolarized $(+50\ \mathrm{mV})$ compared to when it is clamped at 0 mV.

[Part (c) Data from W. N. Zagotta, M. S. Brainard, and R. W. Aldrich, 1988, *J. Neurosci.* **8**:4765–4779.]

Novel Ion Channels Can Be Characterized by a Combination of Oocyte Expression and Patch Clamping

The current traces in Figure 11-22c illustrate the use of the single-channel patch clamp technique to study the properties of voltage-gated K^+ channels. These types of K^+ channels are critical for multiple physiological functions including regulating neuron excitability and cardiac muscle activity. Here a portion of membrane containing a single potassium channel is clamped at a negative membrane potential (a voltage at which these K^+ channels are closed), and then a voltage that depolarizes the membrane — that is, reverse the charge across the membrane. This voltage is applied in two steps; the first raises the membrane potential from the initial potential to 0 mV and the second raises it to 50 mV. Each depolarization results in the channel opening for $\sim$7 ms to allow K^+

ions to flow out of the cell. The efflux of K^+ ions through a single channel can be visualized by the transient rise of the current traces in Figure 11-22c. This experiment illustrates the voltage-dependence of these channels; the channel opens more rapidly and shows greater K^+ current efflux when the depolarization is greater (step to +50 mV) compared to when the depolarization is weaker (step to 0 mV).

Cloning of human-disease-causing genes and sequencing of the human genome have identified many genes encoding putative channel proteins, including 79 putative K^+ channels and 23 putative Na^+ channels. One way of characterizing the function of these proteins is to transcribe a cloned cDNA in a cell-free system to produce the corresponding mRNA. Injecting this mRNA into frog oocytes and taking patch-clamp measurements of the newly synthesized channel protein can often reveal its function (Figure 11-23). This experimental approach is especially useful because frog oocytes normally do not express any channel proteins on their plasma membranes, so only the channel under study is present in the membrane. In addition, because of the large size of frog oocytes, patch-clamping studies are technically easier to perform on them than on smaller cells.

EXPERIMENTAL FIGURE 11-23 The oocyte expression assay is useful in comparing the function of normal and mutant forms of a channel protein. An oocyte from the follicle of a frog is first treated with collagenase to remove the surrounding follicle cells, leaving a denuded oocyte, which is then microinjected with mRNA encoding the channel protein under study.

KEY CONCEPTS OF SECTION 11.4

Nongated Ion Channels and the Resting Membrane Potential

- An inside-negative electric potential (voltage) of between 60 and 90 mV exists across the plasma membrane of all cells.
- The electric potential generated by the selective flow of ions across a membrane can be calculated using the Nernst equation (see Equation 11-2).
- The resting membrane potential in animal cells is the result of the combined action of the ATP-powered Na^+/K^+ pump, which establishes Na^+ and K^+ concentration gradients across the membrane, and resting K^+ channels, which permit selective movement of K^+ ions back down their concentration gradient to the external medium (see Figure 11-3).
- Unlike the more common gated ion channels, which open only in response to various signals, the nongated resting K^+ channels are usually open.
- In plants and fungi, the membrane potential is maintained by the ATP-driven pumping of protons from the cytosol to the exterior of the cell.
- K^+ channels are assembled from four identical subunits, each of which has at least two conserved membrane-spanning α helices and a nonhelical P segment that lines the ion pore and forms the selectivity filter (see Figure 11-20).
- The ion specificity of K^+ channels is due mainly to binding of the dehydrated K^+ ion with eight carbonyl oxygen atoms of specific amino acids in the P segments, which lowers the activation energy for the passage of K^+ compared with Na^+ or other ions (see Figure 11-21).
- The pore in Na^+ channels is wider than in K^+ channels and transports partially hydrated Na^+ ions.
- Patch-clamping techniques, which permit measurement of ion movements through single channels, are used to determine the ion conductivity of a channel and the effect of various reagents on its activity (see Figure 11-22).
- Recombinant DNA techniques and patch clamping allow the expression and functional characterization of channel proteins in frog oocytes (see Figure 11-23).

11.5 Cotransport by Symporters and Antiporters

In previous sections, we saw how ATP-powered pumps generate ion concentration gradients across cellular membranes and how K^+ channels use the K^+ concentration gradient to establish an electric potential across the plasma membrane. In this section, we see how cotransporters use the energy stored in electric potentials and concentration gradients of Na^+ or H^+ ions to power the uphill movement of another substance, which may be a small organic molecule such as glucose, or an amino acid, or a different ion. An important feature of such **cotransport** is that neither substance can move alone; movement of both substances together is obligatory, or *coupled*.

Cotransporters share features with uniporters such as the GLUT proteins. The two types of transporters exhibit certain structural similarities, operate at equivalent rates, and undergo cyclical conformational changes during transport of their substrates. They differ in that uniporters can only accelerate thermodynamically favorable transport down a concentration gradient, whereas cotransporters can harness the energy released when one substance moves down its concentration gradient to drive the movement of another substance against its concentration gradient.

When the transported molecule and cotransported ion move in the same direction, the process is called *symport*; when they move in opposite directions, the process is called *antiport* (see Figure 11-2). Some cotransporters transport only positive ions (cations), while others transport only negative ions (anions). Yet other cotransporters mediate movement of both cations and anions together. Cotransporters are present in all organisms, including bacteria, plants, and animals. In this section, we describe the operation and function of several physiologically important symporters and antiporters.

Na^+ Entry into Mammalian Cells Is Thermodynamically Favored

Mammalian cells express many types of Na^+-linked symporters. The human genome encodes literally hundreds of different types of transporters that use the energy stored in the Na^+ concentration gradient and in the inside-negative electric potential across the plasma membrane to transport a wide variety of molecules into cells against their concentration gradients. To see how such transporters allow cells to accumulate substrates against a considerable concentration gradient, we first need to calculate the change in free energy (ΔG) that occurs during Na^+ entry. As mentioned earlier, two forces govern the movement of ions across a selectively permeable membrane: the voltage across the membrane and the ion

concentration gradient across the membrane. The sum of these forces constitutes the electrochemical gradient. To calculate the free-energy change, ΔG, corresponding to the transport of any ion across a membrane, we need to consider the independent contributions from each of these forces to the electrochemical gradient.

For example, when Na^+ moves from the outside to the inside of a cell, the free-energy change generated from the Na^+ concentration gradient is given by

$$\Delta G_c = RT \ln \frac{[Na_{in}]}{[Na_{out}]} \tag{11-5}$$

At the concentrations of Na_{in} and Na_{out} shown in Figure 11-24, which are typical for many mammalian cells, ΔG_c, the change in free energy due to the concentration gradient, is -6.067 Joules for transport of 1 mole of Na^+ ions from the outside to the inside of a cell, assuming there is no membrane electric potential. Note that the free energy is negative, indicating spontaneous movement of Na^+ into the cell down its concentration gradient.

FIGURE 11-24 Transmembrane forces acting on Na^+ ions. As with all ions, the movement of Na^+ ions across the plasma membrane is governed by the sum of two separate forces: the ion concentration gradient and the membrane electric potential. At the internal and external Na^+ concentrations typical of mammalian cells, these forces usually act in the same direction, making the inward movement of Na^+ ions energetically favorable.

The free-energy change generated from the membrane electric potential is given by

$$\Delta G_{\mathrm{m}} = FE$$

(11-6)

where F is the Faraday constant [$= 96{,}500\,\mathrm{Joules/(mol \cdot V)}$]; and E is the membrane electric potential. If $E = -70\,\mathrm{mV}$, then ΔG_{m}, the free-energy change due to the membrane potential, is –6755 Joules for transport of 1 mole of $\mathrm{Na^+}$ ions from the outside to the inside of a cell, assuming there is no $\mathrm{Na^+}$ concentration gradient. Since both forces do in fact act on $\mathrm{Na^+}$ ions, the total ΔG is the sum of the two partial values:

$$\Delta G = \Delta G_{\mathrm{c}} + \Delta G_{\mathrm{m}} = (-6{,}067) + (-6{,}755) = -12{,}822\ \mathrm{Joules/mol}$$

In this example, the $\mathrm{Na^+}$ concentration gradient and the membrane electric potential contribute almost equally to the total ΔG for transport of $\mathrm{Na^+}$ ions. Since ΔG is less than 0, the inward movement of $\mathrm{Na^+}$ ions is thermodynamically favored. As we will see next, the inward movement of $\mathrm{Na^+}$ is used to power the uphill movement of other ions and several types of small molecules into or out of animal cells. The rapid, energetically favorable movement of $\mathrm{Na^+}$ ions through gated $\mathrm{Na^+}$ channels is also critical in generating action potentials in neurons and muscle cells, as discussed in Chapter 23.

Na^+-Linked Symporters Enable Animal Cells to Import Sugars Including Glucose and Galactose as Well as Amino Acids Against High Concentration Gradients

Most body cells import glucose from the blood *down* a concentration gradient of glucose, using GLUT proteins to facilitate this transport. However, certain cells need to import glucose from extracellular fluids against a very large concentration gradient. For example, the cells lining the small intestine and the kidney tubules need to import glucose from digestive products or urine against a very large concentration gradient because glucose concentration is higher inside the cell. Such cells use a *two-Na^+/one-glucose symporter*, a protein that couples the import of one glucose molecule to the import of two Na^+ ions:

$$2\,\mathrm{Na^+}_{\mathrm{out}} + \mathrm{glucose}_{\mathrm{out}} \rightleftharpoons 2\,\mathrm{Na^+}_{\mathrm{in}} + \mathrm{glucose}_{\mathrm{in}}$$

Quantitatively, the free-energy change for the symport of two Na^+ ions and one glucose molecule can be written

$$\Delta G = RT\,\ln\frac{[\mathrm{glucose}_{\mathrm{in}}]}{[\mathrm{glucose}_{\mathrm{out}}]} + 2RT\ln\frac{[\mathrm{Na^+}_{\mathrm{in}}]}{[\mathrm{Na^+}_{\mathrm{out}}]} + 2FE \tag{11-7}$$

Thus the ΔG for the overall reaction is the sum of the free-energy changes generated by the glucose concentration gradient (1 molecule transported), the Na^+ concentration gradient (2 Na^+ ions transported), and the membrane potential (2 Na^+ ions transported). As illustrated in Figure 11-25, the movement of Na^+ ions into a mammalian cell down their electrochemical gradient has a free-energy change, ΔG, of about $-12{,}552$ Joules per mole of Na^+ transported. Thus the ΔG for the transport of two moles of Na^+ inward would be twice this amount, or about $-25{,}104$ Joules. This negative free-energy change for sodium import is coupled to the uphill transport of glucose, a process with a positive ΔG. We can calculate the glucose concentration gradient (inside greater than outside) that can be established by the action of this Na^+-powered symporter by realizing that at equilibrium for Na^+-linked glucose import, $\Delta G = 0$. By substituting the values for sodium import into Equation 11-7 and setting $\Delta G = 0$, we see that

$$0 = RT \ln \frac{[\text{glucose}_{\text{in}}]}{[\text{glucose}_{\text{out}}]} - 25{,}104 \text{ Joules}$$

and we can calculate that at equilibrium, the ratio of $\text{glucose}_{\text{in}}/\text{glucose}_{\text{out}} = \sim 30{,}000$. Thus the inward flow of two moles of Na^+ can generate an intracellular glucose concentration that is $\sim 30{,}000$ times greater than the exterior concentration. If only one Na^+ ion were imported (ΔG of approximately $-12{,}552$ Joules/mol)

per glucose molecule, then the available energy could generate a glucose concentration gradient (inside/outside) of only about 170-fold. Thus by coupling the transport of two Na^+ ions to the transport of one glucose molecule, the two-Na^+/one-glucose symporter permits cells to accumulate a very high concentration of glucose relative to the external concentration. This means that glucose that is present even at very low concentrations in the lumen of the intestine or in the kidney tubules can be efficiently transported into the cells of the lining and not lost from the body.

The high-resolution crystal structure of a bacterial Na^+ galactose symporter was solved in 2008; it provides a model for the function of Na^+ sugar symporters. In this particular symporter (and in select other symporters), the stoichiometry of Na^+ ions to sugar molecules is 1:1 rather than 2:1. As shown in Figure 11-25, the Na^+ galactose symporter contains 14 transmembrane (TM) α helices, with TM domains 2-6 and 7-11 as inverted repeat structures within the membrane. Both N- and C-termini extend into the periplasm, the gel-like matrix in the space between the inner cytosolic membrane and the bacterial outer membrane. The galactose and Na^+ ions interact with specific side chains of the TM α helices that are present in their binding sites. Substrates enter from the periplasm through an extracellular cavity in the transporter. Upon substrate binding, the extracellular cavity closes and a cavity on the cytosolic side opens, releasing Na^+ and galactose into the cytoplasm. All substrates must bind to their sites on the extracellular domain

before the protein undergoes the change that converts the substrate-binding sites from the outward- to the inward-facing conformation; this ensures that inward transport of galactose and Na^+ ions are coupled. Figure 11-25c shows a model comparing the alternating access model of the Na^+ glucose symporter with a glucose uniporter, which does not require a cotransported ion (compare with Figure 11-5).

FIGURE 11-25 Structure and mechanism of transport by the Na^+ galactose symporter vSGLT from *Vibrio parahaemolyticus*. (a) Topology of vSGLT showing TM domains in rainbow colors from N-terminus (blue) to C-terminus (red). TMs 2-6 and TMs 7-11 form inverted repeats, which are highlighted by the gray trapezoids. (b) Outward-facing model through the membrane plane revealing the extracellular cavity in blue highlighting, to which Na^+ (red sphere) and galactose (red and black spheres) bind, triggering a conformational change to an inward-facing structure on the right, with the intracellular cavity (blue highlighting), releasing Na^+ and galactose into the cytoplasm. The conformational change involves structural rearrangements of TM helices. (c) A model of the pore of a Na^+-glucose symporter (SGLT1) and a glucose uniporter (GLUT2), which function together to transport glucose across the intestinal epithelium (see Figure 11-30). In the Na^+-glucose symporter, the rotation of TM helices underlies an alternating access mechanism in which the pore alternates between being closed (gated) on the extracellular and intracellular sides of the membrane; in the glucose uniporter, rotation of the two domains of the transporter against each other alternately exposes the substrate-binding site to the intracellular and extracellular sides of the membrane (see Figure 11-5).

[Data from S. Faham, 2008, *Science* **321**:810–814; and N. K. Karpowich and D. N. Weng, 2008, *Science* **321**:781–782.]

There are two human Na^+/glucose symporters. SGLT1 is found in the absorptive cells lining the small intestine as well as in the epithelial cells lining part of the kidney tubules. SGLT2 is found only in kidney tubules, where, together with SGLT1, it resorbs glucose into the blood from the forming urine. Inhibition of SGLT2 leads to excretion of glucose in the urine and a reduction in blood glucose levels; therefore, SGLT2 inhibitors have potential use in the treatment of type II diabetes. Indeed, several drug candidates that selectively inhibit SGLT2 and not SGLT1 have been developed or are currently undergoing clinical trials, including several that have been approved by the FDA for use in the United States and Canada.

Cells use Na^+-powered symporters to transport substances other than glucose into the cell against high concentration gradients. For example, several types of Na^+/amino acid symporters allow cells to import many amino acids. As another example, Na^+/neurotransmitter symporters couple the import of Na^+ to the reuptake and recycling of neurotransmitters, and they are the targets of many therapeutic drugs, including many antidepressants. They are also the targets of several drugs of abuse, including cocaine and amphetamines. ■

A Bacterial Na^+/Amino Acid Symporter Reveals How Symport

Works

Until recently, no three-dimensional structure had been determined for any mammalian Na^+-linked symporter, but the structures of several homologous bacterial Na^+/substrate symporters, such as the bacterial Na^+-galactose symporter, have provided considerable insights into the mechanisms of symporter function. The structure of the bacterial two-Na^+/one-leucine symporter has served as a particularly useful model for understanding how antidepressants work, since the bacterial symporter is closely related to the human neurotransmitter transporters that are the targets of many antidepressant drugs.

As shown in Figure 11-26a, the bacterial two-Na^+/one-leucine symporter consists of 12 membrane-spanning α helices. Two of the helices (numbers 1 and 6) have nonhelical segments in the middle of the membrane that form part of the leucine-binding site. The amino acid residues involved in binding the leucine and the two Na^+ ions are located in the middle of the membrane-spanning segment and are close together in three-dimensional space. This proximity suggests that the coupling of amino acid and ion transport in these transporters is the consequence of direct or nearly direct physical interactions of the substrates. Indeed, one of the Na^+ ions is bound to the carboxyl group of the transported leucine (Figure 11-26b). Thus neither substance can bind to the transporter without the other. Each of the two Na^+ ions is bound to six oxygen atoms in the

transporter. One of the two Na^+ ions, for example, is bound to carbonyl oxygens of several transporter amino acids as well as to carbonyl oxygens and the hydroxyl oxygen of one threonine. Equally importantly, there are no water molecules surrounding either of the bound Na^+ atoms, as is the case for K^+ ions in potassium channels (see Figure 11-20). Thus as the Na^+ ions lose their water of hydration in binding to the transporter, they bind to six oxygen atoms with a similar geometry. This reduces the energy change required for the binding of Na^+ ions and prevents other ions, such as K^+, from binding in place of Na^+.

FIGURE 11-26 Three-dimensional structure of the two-Na^+/one-leucine symporter from the bacterium *Aquifex aeolicus*. (a) The bound L-leucine, two Na^+ ions, and a Cl^- ion are

shown in yellow, purple, and green, respectively. The three membrane-spanning α helices that bind the Na^+ or the leucine are colored brown, blue, and orange. (b, c) Binding of the two Na^+ ions to carbonyl main-chain or carboxyl side-chain oxygen atoms (red) that are part of helices 1 (brown), 6 (blue), or 8 (orange). It is important that one of the Na^+ ions is also bound to the carboxyl group of the transported leucine (b).

[Data from A. Yamashita et al., 2005, *Nature* **437**:215, PDB ID 2a65.]

One striking feature of the structure depicted in Figure 11-26 is that the bound Na^+ ions and leucine are *occluded* — that is, they cannot diffuse out of the protein to either the surrounding extracellular or cytoplasmic media. This structure represents an intermediate in the transport process in which the transporter appears to be changing from a conformation with an exoplasmic-facing to one with a cytosolic-facing binding site.

A Na^+-Linked Ca^{2+} Antiporter Regulates the Strength of Cardiac Muscle Contraction

In all muscle cells, a rise in the cytosolic Ca^{2+} concentration triggers contraction. Thus when muscle is resting, the cytosolic Ca^{2+} concentration must be low. In cardiac muscle cells, a *three-Na^+/one-Ca^{2+} antiporter*, rather than the plasma-membrane Ca^{2+} ATPase discussed earlier, plays the principal role in maintaining a low

concentration of Ca^{2+} in the cytosol. The transport reaction mediated by this *cation antiporter* can be written as

$$3\,Na^{+}{}_{out} + Ca^{2+}{}_{in} \rightleftharpoons 3\,Na^{+}{}_{in} + Ca^{2+}_{out}$$

Note that the inward movement of three Na^{+} ions is required to power the export of one Ca^{2+} ion from the cytosol, which has a [Ca^{2+}] of $\sim 2 \times 10^{-7}$ M, to the extracellular medium, which has a [Ca^{2+}] of $\sim 2 \times 10^{-3}$ M — a concentration gradient of some 10,000-fold (higher on the outside). By lowering cytosolic Ca^{2+}, operation of the Na^{+}/Ca^{2+} antiporter reduces the strength of heart muscle contraction.

The Na^{+}/K^{+} ATPase in the plasma membrane of cardiac muscle cells, as in other body cells, creates the Na^{+} concentration gradient necessary for export of Ca^{2+} by the Na^{+}-linked Ca^{2+} antiporter. As mentioned earlier, inhibition of the Na^{+}/K^{+} ATPase by the drugs ouabain and digoxin lowers the cytosolic K^{+} concentration and, more importantly here, simultaneously increases cytosolic Na^{+}. The resulting reduced Na^{+} electrochemical gradient across the membrane causes the Na^{+}-linked Ca^{2+} antiporter to function less efficiently. As a result, fewer Ca^{2+} ions are exported, and the cytosolic Ca^{2+} concentration increases, causing the muscle to contract more strongly. Because of their ability to increase the force of heart muscle contractions, drugs such

as ouabain and digoxin that inhibit the Na^+/K^+ ATPase are widely used in the treatment of congestive heart failure. ■

Several Cotransporters Regulate Cytosolic pH

The anaerobic metabolism of glucose yields lactic acid, and aerobic metabolism yields CO_2, which combines with water to form carbonic acid (H_2CO_3). These weak acids dissociate, yielding H^+ ions (protons); if these excess protons were not removed from cells, the cytosolic pH would drop precipitously, endangering cellular functions. Two types of cotransporters help remove some of the excess protons generated during metabolism in animal cells. One is a $Na^+HCO_3{}^-/Cl^-$ *antiporter*, which imports one Na^+ ion, together with one $HCO_3{}^-$, in exchange for export of one Cl^- ion. The cytosolic enzyme *carbonic anhydrase* catalyzes the hydration of carbon dioxide and the dehydration of bicarbonate to convert water and carbon dioxide to carbonic acid, which dissociates to create H^+ and bicarbonate. Carbonic anhydrase is a zinc metalloenzyme, and zinc binding causes deprotonation of water to create a zinc-hydroxide intermediate that attacks carbon dioxide to generate bicarbonate.

$$HCO_3{}^- + H^+ \overset{\text{Carbonic anhydrase}}{\rightleftharpoons} CO_2 + H_2O$$

Thus the overall action of this enzyme is to *consume* cytosolic H^+ ions, thereby *raising* the cytosolic pH. Also important in raising cytosolic pH is a Na^+/H^+ *antiporter*, which couples the movement of one Na^+ ion into the cell down its concentration gradient to the export of one H^+ ion.

Under certain circumstances, the cytosolic pH can rise beyond the normal range of 7.2–7.5. To cope with the excess OH^- ions associated with elevated pH, many animal cells use an *anion antiporter* that catalyzes a one-for-one exchange of HCO_3^- for Cl^- across the plasma membrane. At high pH, this Cl^-/HCO_3^- *antiporter* exports one molecule of HCO_3^- (which can be viewed as a "complex" of OH^- and CO_2) in exchange for the import of one molecule of Cl^-, thus lowering the cytosolic pH. The movement of Cl^- down its concentration gradient ($Cl^-_{exterior} > Cl^-_{cytosol}$; see Table 11-2) powers the export of HCO_3^-.

The activity of all three of these antiporters is regulated by the cytosolic pH, providing cells with a finely tuned mechanism for controlling cytosolic pH. The two antiporters that operate to increase cytosolic pH are activated when the pH of the cytosol falls. Similarly, a rise in pH above 7.2 stimulates the Cl^-/HCO_3^- antiporter, leading to a more rapid export of HCO_3^- and a drop in the cytosolic pH. In this manner, the cytosolic pH of growing cells is maintained very close to pH 7.4.

An Anion Antiporter Is Essential for Transport of CO_2 by Erythrocytes

Transmembrane anion exchange is essential for an important function of erythrocytes: the transport of waste CO_2 from peripheral tissues to the lungs for exhalation. Waste CO_2 released from cells into the capillary blood freely diffuses across the erythrocyte membrane (Figure 11-27a). In its gaseous form, CO_2 dissolves poorly in aqueous solutions such as the cytosol or blood plasma, as is apparent to anyone who has opened a bottle of a carbonated beverage. However, the large amount of the potent enzyme carbonic anhydrase in the erythrocyte combines CO_2 with hydroxyl ions (OH^-) to form water-soluble bicarbonate ($HCO_3{}^-$) anions. This process occurs while erythrocytes are in systemic (tissue) capillaries and releasing oxygen into the blood plasma. The release of oxygen from hemoglobin induces a change in its conformation that enables a histidine side chain of a globin polypeptide to bind a proton. Thus when erythrocytes are in systemic capillaries, water is split into a proton that binds hemoglobin and an OH^- that reacts with CO_2 to form an $HCO_3{}^-$ anion.

FIGURE 11-27 Carbon dioxide transport in blood requires a Cl^-/HCO_3^- antiporter. (a) In systemic capillaries, carbon dioxide gas diffuses across the erythrocyte plasma membrane and is converted into soluble HCO_3^- by the enzyme carbonic anhydrase; at the same time, oxygen leaves the cell and hemoglobin binds a proton. The anion antiporter AE1 (purple) catalyzes the reversible exchange of Cl^- and HCO_3^- ions across the membrane. The overall reaction causes HCO_3^- to be released from the cell, which is essential for maximal CO_2 transport from the tissues to the lungs and for maintaining pH neutrality in the erythrocyte. (b) In the lungs, where carbon dioxide is excreted, the overall reaction is reversed. See text for additional discussion.

In a reaction catalyzed by the antiporter *Anion Exchanger 1 (AE1)*, also known as *Band 3 anion transporter*, cytosolic HCO_3^- is transported out of the erythrocyte in exchange for an entering Cl^- anion:

$$HCO_3^-{}_{in} + Cl^-{}_{out} \rightleftharpoons HCO_3^-{}_{out} + Cl^-{}_{in}$$

(see Figure 11-27a). The entire anion-exchange process is completed within 50 milliseconds (ms). If anion exchange did not occur, then during periods such as exercise, when much CO_2 is generated,

HCO_3^- would accumulate inside the erythrocyte to toxic levels, as the cytosol would become alkaline. The exchange of HCO_3^- (equal to $OH^- + CO_2$) for Cl^- causes the cytosolic pH to remain nearly neutral. Normally, about 80 percent of the CO_2 in blood is transported as HCO_3^- generated inside erythrocytes; anion exchange allows about two-thirds of this HCO_3^- to be transported by blood plasma external to the cells, increasing the amount of CO_2 that can be transported from tissues to the lungs. In the lungs, where CO_2 leaves the body, the overall direction of this anion-exchange process is reversed (Figure 11-27b).

AE1 catalyzes the precise one-for-one sequential exchange of anions on opposite sides of the plasma membrane required to preserve electroneutrality in the cell; only once every 10,000 or so transport cycles does an anion move from one side of the membrane to the other without another anion moving across the membrane in the opposite direction. AE1 is the most abundant membrane protein in erythrocytes, with nearly one million molecules per cell. The recently solved crystal structure of human erythrocyte AE1 reveals that it has 14 transmembrane α helices and a cytosolic-facing domain that anchors certain cytoskeletal proteins, including ankyrin (see Figure 17-21), to the membrane. The 14 transmembrane α helices form two structurally distinct domains within the membrane, defined as the core and the gate (Figure 11-28a). The core and the gate are divided by a cleft, which, in the outward-facing conformation of the protein whose structure was

solved, is on the extracellular side of the protein. The anion binding site (for chloride) is formed by positively charged dipoles between two of the α helices within the core domain. Comparison of the AE1 structure to the structures of related transporters, such as the Na^+ leucine transporter shown in Figure 11-26, suggests that the antiporter uses an alternating access mechanism: the chloride ion binds the anion binding site in the outward-facing protein, triggering conformational changes such that the core domain rotates against the gate domain to form an inward-facing structure. The chloride ion diffuses out to be replaced by bicarbonate, followed by a reversal of this process.

FIGURE 11-28 The antiporter Anion Exchanger 1 (AE1) transports HCO_3^- out of the cell and Cl^- into the cell. (a) Topology of Human AE1, with 14 transmembrane domains (TMs) drawn as cylinders viewed in the plane of the membrane, showing the core domain in yellow and the gate in blue. The putative binding site is located between TM domain 3 (cyan) and TM 10 (orange). (b) HCO_3^- and Cl^- bind in the anion binding site between TMs 3 and 10. The anions are transported across the membrane via an alternating access mechanism triggered by the relative movements of the core and gate domains.

Numerous Transport Proteins Enable Plant Vacuoles to Accumulate Metabolites and Ions

The lumen of a plant vacuole is much more acidic (pH 3–6) than is the cytosol (pH 7.5). The acidity of vacuoles is maintained by a V-class ATP-powered proton pump (see Figure 11-9) and by a pyrophosphate-powered proton pump that is unique to plants. Both of these pumps, located in the vacuolar membrane, import H^+ ions into the vacuolar lumen against a concentration gradient. The vacuolar membrane also contains Cl^- and NO_3^- channels that transport these anions from the cytosol into the vacuole. The proton pumps generate an inside-positive electric potential that drives the entry of these anions against their concentration gradients. The combined operation of these proton pumps and anion channels produces an inside-positive electric potential of about 20 mV across the vacuolar membrane as well as a substantial pH gradient (Figure 11-29).

FIGURE 11-29 Concentration of ions and sucrose by the plant vacuole. The vacuolar membrane contains two types of proton pumps (orange): a V-class H^+ ATPase (*left*) and a pyrophosphate-hydrolyzing proton pump (*right*) that differs from all other ion pumps and is probably unique to plants. These pumps generate a low luminal pH as well as an inside-positive electric potential across the vacuolar membrane by their inward pumping of H^+ ions. The inside-positive potential powers the movement of Cl^- and NO_3^- from the cytosol through separate channel proteins (purple). Proton antiporters (green), powered by the H^+ gradient, accumulate Na^+, Ca^{2+}, and sucrose inside the vacuole. See B. J. Barkla and O. Pantoja, 1996, *Annu. Rev. Plant Phys.* **47**:159–184; and P. A. Rea et al., 1992, *Trends Biochem. Sci.* **17**:348.

The proton electrochemical gradient across the plant vacuole membrane is used in much the same way as the Na^+ electrochemical gradient across the animal-cell plasma membrane:

to power the selective uptake or extrusion of ions and small molecules by various antiporters. In the leaf, for example, excess sucrose generated by photosynthesis during the day is stored in the vacuole; during the night, the stored sucrose moves into the cytoplasm and is metabolized to CO_2 and H_2O with concomitant generation of ATP from ADP and P_i. A *proton/sucrose antiporter* in the vacuolar membrane operates to accumulate sucrose in plant vacuoles. The inward movement of sucrose is powered by the outward movement of H^+, which is favored by its concentration gradient (lumen > cytosol) and by the cytosolic-negative potential across the vacuolar membrane (see Figure 11-29). Uptake of Ca^{2+} and Na^+ into the vacuole from the cytosol against their concentration gradients is similarly mediated by proton antiporters.

Our understanding of the transporters in plant vacuolar membranes has the potential for increasing agricultural production in soils with a high salt (NaCl) concentration, which are found throughout the world. Because most agriculturally useful crops cannot grow in such saline soils, agricultural scientists have long sought to develop salt-tolerant plants by traditional breeding methods. With the availability of the cloned gene encoding the vacuolar Na^+/H^+ antiporter, researchers can now produce transgenic plants that overexpress this transporter, leading to increased sequestration of Na^+ in the vacuole. For instance, transgenic tomato plants that overexpress the vacuolar Na^+/H^+ antiporter can grow, flower, and produce fruit in the presence of soil

NaCl concentrations that kill wild-type plants. Interestingly, although the leaves of these transgenic tomato plants accumulate large amounts of salt, the fruit has a very low salt content. ■

KEY CONCEPTS OF SECTION 11.5

Cotransport by Symporters and Antiporters

- The electrochemical gradient across a semipermeable membrane determines the direction of ion movement through transmembrane proteins. The two forces constituting the electrochemical gradient — the membrane electric potential and the ion concentration gradient — may act in the same or opposite directions (see Figure 11-25).
- Cotransporters use the energy released by movement of an ion (usually H^+ or Na^+) down its electrochemical gradient to power the import or export of a small molecule or different ion against its concentration gradient.
- The Na^+ galactose symporter provides a model for Na^+ glucose and other sugar transporters. Binding of Na^+ and galactose causes specific TM helices to rotate, creating a gating mechanism that provides alternate access to the substrates on the extracellular and cytoplasmic sides of the membrane.
- The cells lining the small intestine and kidney tubules contain symporters that couple the energetically favorable entry of Na^+ to the import of glucose against its concentration gradient (see Figure 11-26). Amino acids also enter cells by means of Na^+-linked symporters.
- The molecular structure of a bacterial Na^+/amino acid symporter reveals how binding of Na^+ and leucine are coupled and provides a snapshot of an occluded transport intermediate in which the bound substrates cannot diffuse out of the protein (see Figure 11-27).
- In cardiac muscle cells, the export of Ca^{2+} is coupled to and powered by the import of Na^+ by a cation antiporter, which transports three Na^+ ions inward for each Ca^{2+} ion exported.
- Two cotransporters that are activated at low pH help maintain the cytosolic pH in animal cells very close to 7.4 despite metabolic production of carbonic and lactic acids. One, a Na^+/H^+ antiporter, exports excess protons. The other, a $Na^+HCO_3{}^-/Cl^-$ cotransporter, imports $HCO_3{}^-$, which dissociates in the cytosol to yield pH-raising OH^- ions.

- A $Cl^-/HCO_3{}^-$ antiporter that is activated when the cytosolic pH rises above normal decreases pH by exporting $HCO_3{}^-$.
- AE1, a $Cl^-/HCO_3{}^-$ antiporter in the erythrocyte membrane, increases the ability of blood to transport CO_2 from tissues to the lungs (see Figure 11-28).
- The structure of human erythrocyte AE1 has been solved, revealing that anions are transported across the membrane by means of an alternating access mechanism triggered by the relative movements of the core and gate domains.
- Uptake of sucrose, Na^+, Ca^{2+}, and other substances into plant vacuoles is carried out by proton antiporters in the vacuolar membrane. Ion channels and proton pumps in the membrane are critical in generating a large enough proton concentration gradient to power these proton antiporters (see Figure 11-29).

11.6 Transcellular Transport

The previous sections have illustrated how several types of transporters function together to carry out important cellular functions. Here we extend this concept by focusing on the transport of several types of molecules and ions across *polarized* cells, which are cells that are asymmetric (have different "sides") and thus have biochemically distinct regions of the plasma membrane. A particularly well-studied class of polarized cells includes many of the epithelial cells that form sheet-like layers (epithelia) covering most external and internal surfaces of body organs. (Epithelial cells are discussed in greater detail in Chapter 20.) Like many epithelial cells, an intestinal epithelial cell that absorbs nutrients from the gastrointestinal tract has a plasma membrane organized into two major discrete regions: the surface that faces the outside of the organism, called the **apical**, or top, surface, and the surface that faces the inside of the organism (or the bloodstream-facing side), called the **basolateral** surface, which is composed of the basal and lateral surfaces of the cell (see Figure 20-11).

Specialized regions of the epithelial-cell plasma membrane, called **tight junctions**, separate the apical and basolateral membranes and prevent many, but not all, water-soluble substances on one side from moving across to the other side through the extracellular space between cells. For this reason, many nutrients are absorbed from the intestinal lumen across the epithelial cell layer and eventually

into the blood by a two-stage process called **transcellular transport**: molecules are imported through the plasma membrane on the apical side of the cells and exported through the plasma membrane on the basolateral (blood-facing) side (Figure 11-30, also see Figure 11-25d). The apical portion of the plasma membrane, which faces the intestinal lumen, is specialized for absorption of sugars, amino acids, and other molecules that are produced from food by multiple digestive enzymes.

FIGURE 11-30 Transcellular transport of glucose from the intestinal lumen into the blood. The Na^+/K^+ ATPase in the basolateral surface membrane generates Na^+ and K^+ concentration gradients (step 1). The outward movement of K^+ ions through nongated K^+ channels generates an inside-negative membrane potential across the entire plasma membrane. Both the Na^+ concentration gradient and the membrane potential are used to drive the uptake of glucose from the intestinal lumen by the two-Na^+/one-glucose symporter located in the apical surface membrane (step 2). Glucose leaves

the cell via facilitated transport catalyzed by GLUT2, a glucose uniporter located in the basolateral membrane (step 3).

Multiple Transport Proteins Are Needed to Move Glucose and Amino Acids Across Epithelia

Figure 11-30 depicts the proteins that mediate absorption of glucose from the intestinal lumen into the blood. This figure illustrates the important concept that different types of proteins are localized to the apical and basolateral membranes of epithelial cells. The passage of K^+ and Na^+ ions through nongated K^+ channels and through the Na^+/K^+ ATPase generates K^+ and Na^+ gradients as well as an inside-negative membrane potential. The Na^+ concentration gradient and the membrane potential are used to drive the uptake of glucose, against its concentration gradient, from the intestinal lumen into the cell by the two-Na^+/one-glucose symporter located in the apical surface membrane. As noted above, this symporter couples the energetically unfavorable inward movement of one glucose molecule to the energetically favorable inward transport of two Na^+ ions. In the steady state, all the Na^+ ions transported from the intestinal lumen into the cell during Na^+/glucose symport, or the similar process of Na^+/amino acid symport that also takes place on the apical membrane, are pumped out across the basolateral membrane, which faces the blood. Thus the low intracellular Na^+

concentration is maintained. The Na^+/K^+ ATPase that accomplishes this pumping is found exclusively in the basolateral membrane of intestinal epithelial cells. The coordinated operation of these two transport proteins allows uphill movement of glucose and amino acids from the intestine into the cell. This first stage in transcellular transport is ultimately powered by ATP hydrolysis by the Na^+/K^+ ATPase.

In the second stage, the glucose and amino acids concentrated inside intestinal cells by apical symporters are exported down their concentration gradients into the blood via uniport proteins in the basolateral membrane. In the case of glucose, this movement is mediated by GLUT2 (see Figure 11-30 and Figure 11-25d). As noted earlier, this GLUT isoform has a relatively low affinity for glucose but increases its rate of transport substantially when the glucose gradient across the membrane rises (see Figure 11-4).

The net result of this two-stage process is movement of Na^+ ions, glucose, and amino acids from the intestinal lumen across the intestinal epithelium into the extracellular medium that surrounds the basolateral surface of intestinal epithelial cells, and eventually into the blood. Tight junctions between the epithelial cells prevent these molecules from diffusing back into the intestinal lumen. The transport of salt, glucose, and amino acids across the intestinal epithelium increases osmotic pressure and thereby draws water from the intestinal lumen, mainly through the tight junctions, into

the extracellular medium that surrounds the basolateral surface; aquaporins do not appear to play a major role. In a sense, salts, glucose, and amino acids "carry" the water along with them.

Simple Rehydration Therapy Depends on the Osmotic Gradient Created by Absorption of Glucose and Na^+

An understanding of osmosis and the intestinal absorption of salt and glucose forms the basis for a simple therapy that saves millions of lives each year, particularly in developing countries. In these countries, cholera and other intestinal pathogens are major causes of death for young children. A toxin released by these bacteria activates chloride secretion from the apical surfaces of intestinal epithelial cells into the lumen; water follows osmotically, and the resultant massive loss of water causes diarrhea, dehydration, and ultimately death. A cure demands not only killing the bacteria with antibiotics but also *rehydration*: replacement of the water that is lost from the blood and other tissues.

Simply drinking water does not help because it is excreted from the gastrointestinal tract almost as soon as it enters. However, as we have just learned, the coordinated transport of glucose and Na^+ across the intestinal epithelium creates a difference in osmotic pressure across the plasma membrane, forcing water to move from

the intestinal lumen across the epithelial cell layer and ultimately into the blood. Thus giving affected children a solution of sugar and salt to drink (but not sugar or salt alone) increases the transport of sodium and sugar across epithelial cells and, consequently, increases osmotic flow of water into the blood from the intestinal lumen, leading to rehydration. Similar sugar-salt solutions are the basis of popular drinks used by athletes to get sugar as well as water into the body quickly and efficiently. ■

Parietal Cells Acidify the Stomach Contents While Maintaining a Neutral Cytosolic pH

The mammalian stomach contains a 0.1 M solution of hydrochloric acid (HCl). This strongly acidic medium kills many ingested pathogens and denatures many ingested proteins so that they can be degraded by proteolytic enzymes (e.g., pepsin) that function at acidic pH. Hydrochloric acid is secreted into the stomach by specialized epithelial cells called *parietal cells* (also known as *oxyntic cells*) in the stomach lining. These cells contain a H^+/K^+ *ATPase* in the apical membrane (which faces the stomach lumen) that pumps H^+ ions into the stomach in exchange for K^+ ions. The action of this ATPase generates a 1-million-fold H^+ concentration gradient: pH $\sim$1.0 in the stomach lumen versus pH $\sim$7.2 in the cell cytosol. This P-class ATP-powered ion pump is similar in structure and function

to the plasma-membrane Na^+/K^+ ATPase discussed earlier. The numerous mitochondria in parietal cells produce abundant ATP for use by the H^+/K^+ ATPase.

If parietal cells simply exported H^+ ions in exchange for K^+ ions, the loss of protons would lead to a rise in the concentration of OH^- ions in the cytosol and thus a marked increase in cytosolic pH. (Recall that $[H^+] \times [OH^-]$ is always a constant, 10^{-14} M^2.) Parietal cells avoid this rise in cytosolic pH by using Cl^-/HCO_3^- antiporters in the basolateral membrane to export the excess OH^- ions from the cytosol to the blood. As noted earlier, these anion antiporters are activated at high cytosolic pH.

The overall process by which parietal cells acidify the stomach lumen is illustrated in Figure 11-31. In a reaction catalyzed by carbonic anhydrase, the excess cytosolic OH^- combines with CO_2 that diffuses in from the blood, forming HCO_3^-. This bicarbonate ion is exported across the basolateral membrane (and ultimately into the blood) by the Cl^-/HCO_3^- antiporter in exchange for a Cl^- ion. The Cl^- ions then exit through Cl^- channels in the apical membrane, entering the stomach lumen. To preserve electroneutrality, each Cl^- ion that moves into the stomach lumen across the apical membrane is accompanied by a K^+ ion that moves outward through a separate K^+ channel. In this way, the excess K^+ ions pumped inward by the H^+/K^+ ATPase are returned to the stomach lumen, thus maintaining the normal intracellular K^+

concentration. The net result is secretion of equal amounts of H^+ and Cl^- ions (i.e., HCl) into the stomach lumen, while the pH of the cytosol remains neutral and the excess OH^- ions, as HCO_3^-, are transported into the blood, where the change in pH is minimal.

FIGURE 11-31 Acidification of the stomach lumen by parietal cells in the gastric lining. The apical membrane of parietal cells contains a H^+/K^+ ATPase (a P-class pump) as well as Cl^- and K^+ channels. Note the cyclic K^+ transport across the apical membrane: K^+ ions are pumped inward by the H^+/K^+ ATPase and exit via a K^+ channel. The basolateral membrane contains an anion antiporter that exchanges HCO_3^- and Cl^- ions. The combined operation of these four different transport proteins and carbonic anhydrase acidifies the stomach lumen while maintaining the neutral pH of the cytosol.

Bone Resorption Requires the Coordinated Function of a V-Class Proton Pump and a Specific Chloride Channel

Net bone growth in mammals subsides just after puberty, but a finely balanced, highly dynamic process of disassembly (resorption) and reassembly (bone formation) goes on throughout adulthood. Such continual bone *remodeling* permits the repair of damaged bones and can release calcium, phosphate, and other ions from mineralized bone into the blood for use elsewhere in the body.

Osteoclasts, the bone-dissolving cells, are macrophages, a type of cell best known for their role in protecting the body from infections. Osteoclasts are polarized cells that adhere to bone and form specialized, very tight seals between themselves and the bone, creating an enclosed extracellular space (Figure 11-32). An adhered osteoclast then secretes into this space a corrosive mixture of HCl and proteases that dissolves the inorganic components of the bone into Ca^{2+} and phosphate and digests its protein components. The mechanism of HCl secretion is similar to that used by the stomach to generate digestive juice (see Figure 11-31). As in gastric HCl secretion, carbonic anhydrase and an anion antiporter are important for osteoclast function. Osteoclasts employ a V-class

proton pump to export H^+ ions into the bone-facing space, rather than the P-class H^+/K^+ pump used by gastric epithelial cells.

FIGURE 11-32 Dissolution of bone by polarized osteoclast cells requires a V-class proton pump and the ClC-7 chloride channel. The osteoclast plasma membrane is divided into two domains separated by the tight seal between a ring of membrane and the bone surface. The membrane domain facing the bone contains V-class proton pumps and ClC-7 Cl^- channels. The opposing membrane domain contains anion antiporters that exchange HCO_3^- and Cl^- ions. The combined operation of these three transport proteins and carbonic anhydrase acidifies the enclosed space and allows bone resorption while maintaining the neutral pH of the cytosol. See R. Planells-Cases and T. Jentsch, 2009, *Biochim. Biophys. Acta* **1792**:173 for discussion of ClC-7.

The rare hereditary disease *osteopetrosis*, marked by increased bone density, is due to abnormally low bone resorption. Many

patients have mutations in the gene encoding TCIRG1, a subunit of the osteoclast V-class proton pump, whose action is required to acidify the space between the osteoclast and the bone. Other patients have mutations in the gene encoding ClC-7, the chloride channel localized to the domain of the osteoclast plasma membrane that faces the space near the bone. As with lysosomes (see Figure 11-13), in the absence of a chloride channel, the proton pump cannot acidify the enclosed extracellular space, and thus bone resorption is defective. ■

KEY CONCEPTS OF SECTION 11.6

Transcellular Transport

- The apical and basolateral regions of epithelial cell plasma membranes contain different transport proteins and carry out quite different transport processes.
- In intestinal epithelial cells, the coordinated operation of Na^+-linked symporters in the apical membrane and Na^+/K^+ ATPases and uniporters in the basolateral membrane mediates transcellular transport of amino acids and glucose from the intestinal lumen to the blood (see Figure 11-30).
- The increased osmotic pressure created by transcellular transport of salt, glucose, and amino acids across the intestinal epithelium draws water from the intestinal lumen into the body, a phenomenon that serves as the basis for rehydration therapy using sugar-salt solutions.
- The combined action of carbonic anhydrase and four different transport proteins permits parietal cells in the stomach lining to secrete HCl into the lumen while maintaining their cytosolic pH near neutrality (see Figure 11-31).
- Bone resorption requires coordinated function in osteoclasts of a V-class proton pump and the ClC-7 chloride channel (see Figure 11-32).

Review the Concepts

1. Nitric oxide (NO) is a gaseous molecule with lipid solubility similar to that of O_2 and CO_2. Endothelial cells lining arteries use NO to signal surrounding smooth muscle cells to relax, thereby increasing blood flow. What mechanism or mechanisms would transport NO from where it is produced in the cytoplasm of an endothelial cell into the cytoplasm of a smooth muscle cell, where it acts?
2. Acetic acid (a weak acid with a pK_a of 4.75) and ethanol (an alcohol) are each composed of two carbon atoms, hydrogen

and oxygen, and both enter cells by passive diffusion. At pH 7, one is much more able to permeate a cellular membrane than the other. Which is more membrane permeable, and why? Predict how the membrane permeability of each is altered when the extracellular pH is reduced to 1.0, a value typical of the stomach.

3. Uniporters and ion channels support facilitated transport across cellular membranes. Although both are examples of facilitated transport, the rates of ion movement via an ion channel are roughly 10^4- to 10^5-fold faster than the rates of molecule movement via a uniporter. What key mechanistic difference results in this large difference in transport rate? What contribution to free energy (ΔG) determines the direction of transport?
4. Name the three classes of membrane transport proteins. Explain which one or ones of these classes is able to move glucose and which can move bicarbonate (HCO_3^-) against an electrochemical gradient. In the case of bicarbonate, but not glucose, the ΔG of the transport process has two terms. What are these two terms, and why does the second not apply to glucose? Why are cotransporters often referred to as examples of secondary active transport?
5. An H^+ ion is smaller than an H_2O molecule, and a glycerol molecule, a three-carbon alcohol, is much larger. Both readily dissolve in H_2O. Why do aquaporins fail to transport H^+ whereas some can transport glycerol?
6. GLUT1, found in the plasma membrane of erythrocytes, is a classic example of a uniporter.

a. Design a set of experiments to prove that GLUT1 is indeed a glucose-specific uniporter rather than a galactose- or mannose-specific uniporter.
b. Glucose is a six-carbon sugar, and ribose is a five-carbon sugar. Despite its smaller size, ribose is not efficiently transported by GLUT1. How can this be explained?
c. A drop in blood sugar from 5 mM to 2.8 mM or below can cause confusion and fainting. Calculate the effect of this drop on glucose transport into cells expressing GLUT1.
d. How do liver and muscle cells maximize glucose uptake without changing V_{max}?
e. Tumor cells expressing GLUT1 often have a higher V_{max} for glucose transport than do normal cells of the same type. How could these cells increase the V_{max}?
f. Fat and muscle cells modulate the V_{max} for glucose uptake in response to insulin signaling. How?

7. Name the four classes of ATP-powered pumps that produce active transport of ions and molecules. Indicate which of these classes transport only ions and which transport primarily small organic molecules. The initial discovery of one class of these ATP-powered pumps came from studying the transport not of a natural substrate, but rather of artificial substrates used as cancer chemotherapy drugs. What do investigators now think are common examples of the natural substrates of this particular class of ATP-powered pumps?

8. Explain why the coupled reaction $ATP \rightarrow ADP + P_i$ in the P-class ion pump mechanism does not involve direct hydrolysis of the phosphoanhydride bond.
9. Describe a negative feedback mechanism for controlling a rising cytosolic Ca^{2+} concentration in cells that require rapid changes in Ca^{2+} concentration for normal functioning. How would a drug that inhibits calmodulin activity affect cytosolic Ca^{2+} concentration regulation by this mechanism? What would be the effect on the function of, for example, a skeletal muscle cell?
10. Certain proton pump inhibitors that inhibit secretion of stomach acid are among the most widely sold drugs in the world today. What pump does this type of drug inhibit, and where is this pump located?
11. The membrane potential in animal cells, but not in plants, depends largely on resting K^+ channels. How do these channels contribute to the resting membrane potential? Why are these channels considered to be nongated channels? How do these channels achieve selectivity for K^+ versus Na^+, which is smaller than K^+?
12. Patch clamping can be used to measure the conductance properties of individual ion channels. Describe how patch clamping can be used to determine whether or not the gene coding for a putative K^+ channel actually codes for a K^+ or a Na^+ channel.
13. Plants use the proton electrochemical gradient across the vacuole membrane to power the accumulation of salts and sugars in the organelle. This accumulation creates

hypertonic conditions in the vacuole. Why does this not result in the plant cell swelling and bursting? Even under isotonic conditions, there is a slow leakage of ions into animal cells. How does the plasma-membrane Na^+/K^+ ATPase enable animal cells to avoid osmotic lysis under isotonic conditions?

14. In the case of the bacterial two-Na^+/one-leucine symporter, what is the key distinguishing feature of the bound Na^+ ions that ensures that other ions, particularly K^+, do not bind?
15. Describe the symport process by which cells lining the small intestine import glucose. What ion is responsible for the transport, and what two particular features facilitate the energetically favored movement of this ion across the plasma membrane?
16. Movement of glucose from one side to the other side of the intestinal epithelium is a major example of transcellular transport. How does the Na^+/K^+ ATPase power the process? Why are tight junctions essential for the process? Why is localization of the transporters specifically in the apical or basolateral membrane crucial for transcellular transport? Rehydration supplements such as sport drinks include a sugar and a salt; why are both important to rehydration?

CHAPTER 12

Cellular Energetics

Angela M. Barragan

Computer generated image of chromatophores in the photosynthetic purple bacterium *Rhodobacter sphaeroides*. Each chromatophore contains membrane proteins that use light to drive the synthesis of ATP. Energy is absorbed by pigments in two types of light-harvesting complexes (green and red) and transferred to reaction centers (light blue) where high-energy electrons are generated. Their energy is used by pumps (purple) to move protons into the chromatophores, generating a proton gradient. This powers ATP synthase (orange) to convert ADP + P_i to ATP.

12.8 Chloroplasts and Photosynthesis
12.9 Use of Light Energy to Generate Molecular Oxygen, NADPH, and ATP in Stages 1–3 of Photosynthesis
12.10 ATP and NADPH Drive Carbon Fixation in the Calvin Cycle and Carbohydrate Synthesis in Stage 4 of Photosynthesis

From the growth and division of a cell to the beating of a heart to the electrical activity of a neuron that underlies thinking, life requires energy. Energy is defined as the capacity to do work, and on a cellular level, that work includes conducting and regulating a multitude of chemical reactions and transport processes, growing and dividing, generating and maintaining a highly organized structure, and interacting with other cells. This chapter describes the molecular mechanisms by which cells use chemical nutrients or sunlight as sources of energy, with a special focus on how cells convert these external sources of energy into a biologically universal intracellular chemical energy carrier, **adenosine triphosphate**, or **ATP**. ATP, found in all types of organisms and presumably present in the earliest life forms, is generated by the chemical addition of inorganic phosphate (HPO_4^{2-}, often abbreviated as P_i) to adenosine diphosphate, or ADP, a process called *phosphorylation*. Cells use the

energy released during hydrolysis of the terminal phosphoanhydride bond in ATP (see Figures 1-7 and 2-31) to power many otherwise energetically unfavorable processes. Examples include the synthesis of proteins from amino acids and of nucleic acids from nucleotides (see Chapter 4), the transport of molecules against a concentration gradient by ATP-powered pumps (see Chapter 11), the contraction of muscles (see Chapter 17), and the beating of cilia (see Chapter 18). A key theme of cellular energetics is that proteins use, or *couple*, energy released from one process (e.g., ATP hydrolysis) to drive another process (e.g., movement of molecules across membranes) that otherwise would be thermodynamically unfavorable.

The energy to drive ATP synthesis from ADP ($\Delta G^{\circ\prime} = 7.3$ kcal/mol) derives primarily from two sources: the energy in the chemical bonds of nutrients and the energy in sunlight (Figure 12-1). The two processes primarily responsible for converting these energy sources into ATP are **aerobic oxidation** (also known as **aerobic respiration**), which occurs in mitochondria in nearly all eukaryotic cells (see Figure 12-1, *top*), and **photosynthesis**, which occurs only in **chloroplasts**, found in the leaf cells of plants (see Figure 12-1, *bottom*) and in certain single-celled organisms, such as algae and cyanobacteria. Two additional processes, glycolysis and the citric acid cycle (see Figure 12-1, *top left*), are also important direct or indirect sources of ATP in both animal and plant cells.

FIGURE 12-1 Overview of aerobic oxidation and photosynthesis. Eukaryotic cells use two fundamental mechanisms to convert external sources of energy into ATP. *Top:* In aerobic oxidation, "fuel" molecules [primarily sugars and fatty acids (lipids)] undergo preliminary processing in the cytosol, such as breakdown of glucose to pyruvate (**stage I**), and are then transferred into mitochondria, where they are converted by oxidation with O_2 to CO_2 and H_2O (**stages II** and **III**) and ATP is generated (**stage IV**). *Bottom:* In photosynthesis, which occurs in chloroplasts, the radiant energy of light is absorbed by specialized pigments (**stage 1**); the absorbed energy is used both to oxidize H_2O to O_2 and to establish conditions (**stage 2**) necessary for the generation of ATP (**stage 3**) and of carbohydrates from CO_2 (carbon fixation, **stage 4**). Both mechanisms involve the production of reduced high-energy electron carriers ($NADH$, $NADPH$, $FADH_2$) and the movement of electrons down an electric potential gradient in an electron-transport chain through specialized membranes. Energy released from these electrons is captured as a proton electrochemical gradient (proton-motive force) that is then used to drive ATP synthesis. Bacteria use comparable processes.

In aerobic oxidation, breakdown products of sugars (carbohydrates) and fatty acids (hydrocarbons) — both derived from the digestion of food in animals — are converted by oxidation with oxygen (O_2) to carbon dioxide (CO_2) and water (H_2O). The energy released from this overall reaction is transformed into the chemical energy of

phosphoanhydride bonds in ATP. This process is analogous to burning wood (carbohydrates) or oil (hydrocarbons) to generate heat in furnaces or motion in automobile engines: both consume O_2 and generate CO_2 and H_2O. The key difference is that cells break down the overall reaction into many intermediate steps, with the amount of energy released in any given step closely matched to the amount of energy that can be stored — for example, as ATP — or that is required for the next intermediate step. If there were not such a close match, either excess released energy would be lost as heat (which would be very inefficient), or there would not be enough energy released in a step to generate energy storage molecules such as ATP or to drive the next step in the process (which would be ineffective).

In photosynthesis, the radiant energy of light is absorbed by pigments such as chlorophyll and used to make ATP and carbohydrates — primarily sucrose and starch. Unlike aerobic oxidation, which uses carbohydrates and O_2 to generate CO_2, photosynthesis uses CO_2 as a substrate and generates O_2 and carbohydrates as products.

This reciprocal relationship between aerobic oxidation in mitochondria and photosynthesis in chloroplasts underlies a profound symbiotic relationship between photosynthetic and non-photosynthetic organisms. The oxygen generated during photosynthesis is the source of virtually all the oxygen in the air on

our planet, and the carbohydrates produced are the ultimate source of energy for virtually all non-photosynthetic organisms on Earth. (An exception is bacteria living in deep-sea hydrothermal vents — and the organisms that feed on them — which obtain energy for converting CO_2 into carbohydrates by oxidation of geologically generated reduced inorganic compounds released by the vents.)

In this chapter, we explore the structures and functions of mitochondria and chloroplasts and the molecular mechanisms underlying aerobic oxidation and photosynthesis. We will first consider the mechanism, known as **chemiosmosis** (also called *chemiosmotic coupling*), used by mitochondria and chloroplasts in eukaryotic cells and by bacteria to generate ATP from ADP and P_i.

12.1 Chemiosmosis, Electron Transport, the Proton-Motive Force, and ATP Synthesis

Chemiosmosis is based on a simple, yet profound, concept. In Chapter 2 (Section 2.4) we described the three forms of potential, or stored, energy in biology: chemical bond energy, the energy stored in concentration gradients, and that stored in electrical gradients. All three forms are interconvertible. For example, as we learned in Chapter 11, the hydrolysis of ATP, which releases its chemical potential energy, can drive, via ATPase pumps, the formation of chemical concentration gradients and electric voltage gradients across biological membranes. Thus it makes sense that the movement of molecules across membranes and down a chemical concentration gradient or movement of ions (e.g., protons, H^+) down an electric voltage gradient release energy. The released energy could be dissipated as heat or harnessed to drive the synthesis of ATP from ADP and P_i. As we also learned in Chapter 2, in redox reactions electrons can release energy as they move from a higher energy state to a lower energy state (down their electric potential gradient), for example, when they move from atoms or molecules having more negative reduction potentials to those with more positive reduction potentials. The released energy can be used to drive chemical reactions and generate electrical and chemical gradients across membranes.

In chemiosmosis, a proton electrochemical gradient across a membrane is first generated by energy released as electrons travel down their electric potential gradient through an **electron-transport chain**. Electron-transport chains will be described in detail below. The energy stored in the proton electrochemical gradient, called the **proton-motive force**, is then used to power the synthesis of ATP (Figure 12-2) or other energy-requiring processes when the protons move back across the membrane down the electrochemical gradient. As protons move down their electrochemical gradient through the ATP synthesizing enzyme called **ATP synthase**, ATP is generated from ADP and P_i, a process that is the reverse of that mediated by the ATP-powered ion pumps discussed in Chapter 11. In ATP-powered pumps, the energy released by ATP hydrolysis is used to move substances up an electrochemical gradient; in ATP synthase, protons moving down their electrochemical gradient release energy used to make ATP from ADP and P_i. We will review in detail the mechanism by which ATP synthase exploits a proton-based electrochemical gradient to make ATP later in this chapter.

FIGURE 12-2 The proton-motive force powers ATP synthesis. Transmembrane proton concentration and electrical (voltage) gradients, collectively called the *proton-motive force,* are generated during aerobic oxidation and photosynthesis, in both eukaryotes and prokaryotes (bacteria). High-energy electrons (e^-) generated by light absorption by pigments (e.g., chlorophyll, step **1a**), or held in the reduced form of electron carriers (e.g., NADH, $FADH_2$, step **1b**) made during the catabolism of sugars and lipids, pass down an electron-transport chain (blue arrows, step **2**), releasing energy throughout the process. The released energy is used to pump protons across the membrane (red arrows, step **3**), generating the proton-motive force (pH and electric voltage gradients across the membrane). In chemiosmotic coupling, the energy released when protons flow down the gradient through ATP synthase (step **4**) drives the synthesis of ATP (step **5**). The proton-motive force can also power other processes, such as the transport of metabolites across the membrane against their concentration gradient and rotation of bacterial flagella.

KEY CONCEPTS OF SECTION 12.1

Chemiosmosis, Electron Transport, the Proton-Motive Force, and ATP Synthesis

- In a process known as *aerobic oxidation*, cells convert the energy released by the oxidation of glucose or fatty acids into synthesis of the terminal phosphoanhydride bond of ATP.
- Chemiosmosis is based on the interconversion of three forms of biological potential energy: chemical bond energy, chemical gradients across membranes, and electrical (voltage) gradients across membranes.
- The energy released as electrons travel down their electric potential gradient through an electron-transport chain generates a proton electrochemical gradient across a membrane located either in a mitochondrion, a chloroplast, or a bacterial plasma membrane.
- The energy stored in the proton electrochemical gradient is called the *proton-motive force*.
- When protons move back across the membrane down the electrochemical gradient, they release energy.
- The protons move back across the membrane through the ATP-synthesizing enzyme called *ATP synthase*, which harnesses the released energy to make ATP from ADP and P_i.

12.2 First Step of Harvesting Energy from Glucose: Glycolysis

In an automobile engine, hydrocarbon fuel is oxidatively and explosively converted in an essentially one-step process to mechanical work (i.e., driving a piston) plus the products CO_2 and H_2O. The process is relatively inefficient in that substantial amounts of the chemical energy stored in the fuel are wasted, as they are converted to unused heat, and substantial amounts of fuel are only partially oxidized and are sometimes released as toxic exhaust. In the competition to survive, organisms cannot afford to squander their often limited energy sources on an equivalently inefficient process and have therefore evolved a more efficient mechanism for converting fuel into work. That mechanism, known as *aerobic oxidation*, provides the following advantages:

- By dividing the energy conversion process into multiple steps that generate several energy-carrying intermediates, chemical bond energy is efficiently channeled into the synthesis of ATP, with little energy lost as heat.
- Different fuels (sugars and fatty acids) are reduced to common intermediates that can then share subsequent pathways for combustion and ATP synthesis.

Because the total energy stored in the bonds of the initial fuel molecules is substantially greater than that required to drive the

synthesis of a single ATP molecule ($\sim 7.3\,\mathrm{kcal/mol}$), many ATP molecules are produced for each fuel molecule consumed. An important feature of ATP production from the breakdown of nutrient fuels into CO_2 and H_2O is a set of reactions, called **respiration**, involving a series of oxidation and reduction reactions called an *electron-transport chain* (see Figure 12-1, *top*). The combination of these reactions with phosphorylation of ADP to form ATP is called **oxidative phosphorylation** and occurs in mitochondria in nearly all eukaryotic cells. When oxygen is available and is used as the final recipient of the electrons transported via the electron-transport chain, the respiratory process that converts nutrient energy into ATP is called *aerobic oxidation* or *aerobic respiration*. Aerobic oxidation is an especially efficient way to maximize the conversion of nutrient energy into ATP because O_2 is a relatively strong oxidant. If some molecule other than O_2 — for example, the weaker oxidants sulfate ($SO_4{}^{2-}$) or nitrate (NO^{3-}) — is the final recipient of the electrons in the electron-transport chain, the process is called **anaerobic respiration**. Anaerobic respiration is typical of some prokaryotic microorganisms. Although there are exceptions, most known multicellular (metazoan) eukaryotic organisms use aerobic oxidation to generate most of their ATP.

In our discussion of aerobic oxidation, we will be tracing the fate of the two main cellular fuels: sugars (principally glucose) and fatty acids. Under certain conditions — for example, starvation conditions

— amino acids also feed into these metabolic pathways. We first consider glucose oxidation, then turn to fatty acids.

The complete aerobic oxidation of one molecule of glucose yields 6 molecules of CO_2, and the energy released is coupled to the synthesis of as many as 30 molecules of ATP. The overall reaction is

$$C_6H_{12}O_6 + 6\,O_2 + 30\,P_i^{2-} + 30\,ADP^{3-} + 30\,H^+ \rightarrow 6\,CO_2 + 30\,ATP^{4-}$$

Glucose oxidation in eukaryotes takes place in four stages (see Figure 12-1, *top*):

Stage I: Glycolysis In the cytosol, one 6-carbon glucose molecule is converted by a series of reactions to two 3-carbon **pyruvate** molecules; a net of 2 ATPs are produced for each glucose molecule metabolized.

Stage II: Citric Acid Cycle In the **mitochondrion**, the oxidation of pyruvate, generated by glycolysis, to CO_2 is coupled to the generation of the high-energy electron carriers NADH and $FADH_2$, which store the energy for later use. These two carriers can be considered the sources of high-energy electrons.

Stage III: Electron-Transport Chain High-energy electrons flow down their electric potential gradient from NADH and $FADH_2$ to O_2 via membrane proteins that convert the energy released into a proton-motive force (H^+ electrochemical gradient). The energy

released from the electrons pumps protons across a membrane, thus generating the proton gradient.

Stage IV: ATP Synthesis The proton-motive force powers the synthesis of ATP as protons flow down their concentration and electrical (voltage) gradients through the ATP-synthesizing enzyme ATP synthase, which is embedded in a mitochondrial membrane. For each original glucose molecule, an estimated 28 additional ATPs are produced by this mechanism of oxidative phosphorylation (stages II–IV).

In this section, we discuss stage I: the biochemical pathways that break down glucose into pyruvate in the cytosol. We also discuss how these pathways are regulated, and we contrast the metabolism of glucose under anaerobic and aerobic conditions. The ultimate fate of pyruvate, once it enters mitochondria, is discussed in Section 12.5.

During Glycolysis (Stage I), Cytosolic Enzymes Convert Glucose to Pyruvate

Glycolysis, the first stage of glucose oxidation, occurs in the cytosol in both eukaryotes and prokaryotes; it does not require molecular oxygen (O_2) and is thus an anaerobic process. Glycolysis is an example of **catabolism**, the biological breakdown of complex substances into simpler ones. A set of 10 water-soluble cytosolic

enzymes catalyze the reactions constituting the *glycolytic pathway* (*glyco*, “sweet”; *lysis*, “split”), in which one molecule of glucose is converted to two molecules of pyruvate (Figure 12-3). Below we will consider some of the reasons why so many steps are used to efficiently convert glucose to pyruvate.

FIGURE 12-3 The glycolytic pathway. A series of 10 reactions degrades glucose to pyruvate. Two reactions consume ATP, forming ADP and phosphorylated sugars (red), two generate ATP from ADP by substrate-level phosphorylation (green), and one yields NADH by reduction of NAD^+ (yellow). Note that all the intermediates between glucose and pyruvate are

phosphorylated compounds. Steps **1**, **3**, and **10**, with single arrows, are essentially irreversible (have large negative ΔG values) under ordinary conditions in cells.

All the reaction intermediates in glycolysis produced by these enzymes are water-soluble, phosphorylated compounds called *metabolic intermediates*. In addition to chemically converting one glucose molecule into two pyruvates, the glycolytic pathway generates four ATP molecules by phosphorylation of four ADPs (steps **7** and **10**). ATP is formed directly through the enzyme-catalyzed joining of ADP with a P_i that is derived from phosphorylated metabolic intermediates; this process is called **substrate-level phosphorylation** (to distinguish it from the *oxidative phosphorylation* that generates ATP in stages III and IV). Substrate-level phosphorylation in glycolysis, which does not involve the use of a proton-motive force, requires the prior addition (in steps **1** and **3**) of two phosphates from two ATPs. By adding a little energy in the beginning of the pathway, glycolysis can recover more energy downstream. As a consequence, glycolysis yields the net production of only two ATP molecules per glucose molecule.

The balanced chemical equation for the conversion of glucose to pyruvate shows that four hydrogen atoms (four protons and four electrons) are also released:

(For convenience, we show pyruvate here in its un-ionized form, pyruvic acid, although at physiological pH it would be largely dissociated.) All four electrons and two of the four protons are transferred (see Figure 12-3, step **6**) to two molecules of the oxidized form of **nicotinamide adenine dinucleotide** ($\mathbf{NAD^+}$) to produce the reduced form of the coenzyme, NADH (see Figure 2-33a):

$$2\,H^+ + 4\,e^- + 2\,NAD^+ \rightarrow 2\,NADH$$

Later we will see that the energy carried by the high-energy electrons in NADH and the analogous electron carrier $FADH_2$, the reduced form of the coenzyme **flavin adenine dinucleotide (FAD)** (see Figure 2-33b), can be used to make additional ATPs via the electron-transport chain. The overall chemical equation for this first stage of glucose metabolism is

$$C_6H_{12}O_6 + 2\,NAD^+ + 2\,ADP^{3-} + 2\,P_i{}^{2-} \rightarrow 2\,C_3H_4O_3 + 2\,NADH +$$

Why are there so many enzymatic steps and so many metabolic intermediates in the conversion of one glucose to two pyruvates?

One reason is that some of the intermediates can be diverted to the biosynthesis of other molecules needed by cells, such as the conversion of dihydroxyacetone phosphate to glycerol. Another was mentioned previously: by dividing the process into multiple steps, small portions of the high chemical bond energy in glucose can be efficiently channeled in separate steps into the synthesis of ATP (steps **7** and **10**) and NADH (step **6**), with little energy lost as heat. In addition, multiple intermediate steps afford the opportunity to regulate the activities of these steps and related cellular processes either independently or coordinately, thus permitting fine tuning of the metabolic pathway.

After glycolysis, only a fraction of the energy available in glucose has been extracted and converted to ATP and NADH. The rest remains trapped in the covalent bonds of the two pyruvate molecules. The ability to efficiently convert the energy remaining in pyruvate to ATP depends on the presence of molecular oxygen. As we will see when we consider the electron-transport chain (Section 2.5), energy conversion is substantially more efficient under aerobic conditions than under anaerobic conditions.

The Rate of Glycolysis Is Adjusted to Meet the Cell's Need for ATP

To maintain appropriate levels of ATP, cells must control the rate of glucose catabolism. The operation of the glycolytic pathway (stage I), as well as the citric acid cycle (stage II), is continuously regulated, primarily by allosteric mechanisms (see Chapter 3 for general principles of allosteric control). Three allosteric enzymes involved in glycolysis play key roles in regulating the entire glycolytic pathway. *Hexokinase* (see Figure 12-3, step **1**) is inhibited by its reaction product, glucose 6-phosphate. Hexokinase is involved in the regulation of energy metabolism in at least two additional ways by acting as a glucose sensor. Hexokinase isoforms in mammals and plants, but not yeast, bind to and are active on the cytoplasmic surface of the **mitochondrial outer membrane**, apparently coordinating the activities of the cytoplasmic glycolytic system and mitochondrial activity, including respiration, and facilitating efficient, global ATP production. In mammals, plants, and yeast, some hexokinase isoforms can enter the nucleus and act as co-factors for transcription factors to control energy metabolism by regulating the synthesis of several key enzymes. The second allosteric enzyme is *Pyruvate kinase* (see Figure 12-3, step **10**), which is inhibited by ATP, so glycolysis slows down if too much ATP is present. The third enzyme, *phosphofructokinase-1* (see Figure 12-3, step **3**), is the principal rate-limiting enzyme of the glycolytic pathway; it is allosterically controlled by several molecules (Figure 12-4).

FIGURE 12-4 Allosteric regulation of glucose metabolism. The key regulatory enzyme in glycolysis, phosphofructokinase-1, is allosterically activated by AMP and fructose 2,6-bisphosphate, whose concentrations are elevated when the cell's energy stores are low. The enzyme is inhibited by ATP and citrate, both of which are elevated when the cell is actively oxidizing glucose to CO_2 (i.e., when energy stores are high).

For example, phosphofructokinase-1 is allosterically *inhibited* by ATP and allosterically *activated* by adenosine monophosphate (AMP). As a result, the rate of glycolysis is very sensitive to the cell's **energy charge**, a measure of the fraction of total adenosine phosphates that have "high-energy" phosphoanhydride bonds, which is equal to $[(\mathrm{ATP}) + 0.5(\mathrm{ADP})]/[(\mathrm{ATP}) + (\mathrm{ADP}) + (\mathrm{AMP})]$. The allosteric inhibition of phosphofructokinase-1 by ATP may seem unusual because ATP is also a substrate of this enzyme. But the affinity of the substrate-binding site for ATP is much higher (has a lower K_m) than that of the allosteric site. Thus at low concentrations, ATP binds to the catalytic site, but not to the inhibitory allosteric site, and enzymatic catalysis proceeds at near maximal rates. At high concentrations, ATP also binds to the

allosteric site, inducing a conformational change that reduces the affinity of the enzyme for its other substrate, fructose 6-phosphate, and thus reduces the rate of this reaction and the overall rate of glycolysis.

Another important allosteric activator of phosphofructokinase-1 is *fructose 2,6-bisphosphate*. This metabolite is formed from fructose 6-phosphate by an enzyme called *phosphofructokinase-2*. Fructose 6-phosphate accelerates the formation of fructose 2,6-bisphosphate, which in turn activates phosphofructokinase-1. This type of control is known as *feed-forward activation*, in which a high abundance of a metabolite (here, fructose 6-phosphate) accelerates its own subsequent metabolism. Fructose 2,6-bisphosphate allosterically activates phosphofructokinase-1 in liver cells by decreasing the inhibitory effect of high ATP concentrations and by increasing the affinity of phosphofructokinase-1 for one of its substrates, fructose 6-phosphate. In Chapter 21 we will see how the hormone insulin influences energy metabolism via fructose 2,6-bisphosphate. Phosphofructokinase-1 is also inhibited by high concentrations of citrate. Later in this chapter we will see that citrate is a product generated during stage II of glucose oxidation.

The three glycolytic enzymes that are regulated by allostery catalyze reactions with large negative $\Delta G^{\circ\prime}$ values — reactions that are essentially irreversible under ordinary conditions. These enzymes are therefore particularly suitable for regulating the entire glycolytic

pathway. Additional control is exerted by glyceraldehyde 3-phosphate dehydrogenase, which catalyzes the reduction of NAD^+ to NADH (see Figure 12-3, step **6**). As we shall see, NADH is a high-energy electron carrier used subsequently during oxidative phosphorylation in mitochondria. If cytosolic NADH builds up owing to a slowdown in mitochondrial oxidation, step **6** becomes thermodynamically less favorable.

Glucose metabolism is controlled differently in various mammalian tissues to meet the metabolic needs of the organism as a whole. For instance, when glucose is not available in the diet, it is necessary for the liver to provide that glucose by releasing it into the bloodstream. To do this, the liver converts the polymer glycogen, a storage form of glucose (see Chapter 2), directly to glucose 6-phosphate (without involvement of hexokinase, see Figure 12-3, step **1**). Under these conditions, there is a reduction in fructose 2,6-bisphosphate levels and decreased phosphofructokinase-1 activity (see Figure 12-4). As a result, glucose 6-phosphate derived from glycogen is not metabolized to pyruvate; rather, it is converted to glucose by a phosphatase and released into the blood to nourish the brain and red blood cells, which depend primarily on glucose for their energy. In all cases, the activity of these regulated enzymes is controlled by the level of small-molecule metabolites, generally by allosteric interactions, or by hormone-mediated phosphorylation and dephosphorylation reactions. (Chapters 15 and 21 provide more

detailed discussions of hormonal control of glucose metabolism in liver and muscle.)

Glucose Is Fermented When Oxygen Is Scarce

Many eukaryotes, including humans, are *obligate aerobes*: they thrive only in the presence of molecular oxygen and can metabolize glucose (or related sugars) completely to CO_2, with the concomitant production of a large amount of ATP. Most eukaryotes, however, can generate some ATP by anaerobic metabolism. A few eukaryotes are *facultative anaerobes*: they grow in either the presence or the absence of oxygen. Annelids (segmented worms), mollusks, and some yeasts, for example, can survive without oxygen, relying on the ATP produced by fermentation.

In the absence of oxygen, yeasts convert the pyruvate produced by glycolysis to one molecule each of ethanol and CO_2; in these reactions, two NADH molecules are oxidized to NAD^+ for every two pyruvates converted to ethanol, thereby regenerating the supply of NAD^+, which is necessary for glycolysis to continue (Figure 12-5a, *left*). This anaerobic catabolism of glucose, called **fermentation**, is the basis of beer and wine production.

FIGURE 12-5 Anaerobic versus aerobic metabolism of glucose. The ultimate fate of pyruvate formed during glycolysis depends on the presence or absence of oxygen. (a) In the absence of oxygen, pyruvate is only partially degraded and no further ATP is made. However, two electrons are transferred from each NADH molecule produced during glycolysis to an acceptor molecule to regenerate NAD^+, which is required for continued glycolysis. In yeast (*left*), acetaldehyde is the electron acceptor and ethanol is the product. This process is called *alcoholic fermentation*. When oxygen is scarce in muscle cells (*right*), NADH reduces pyruvate

to form lactic acid, regenerating NAD^+, a process called *lactic acid fermentation*. (b) In the presence of oxygen, pyruvate is transported into mitochondria, where it is first converted by pyruvate dehydrogenase into one molecule of CO_2 and one of acetic acid, the latter linked to coenzyme A (CoA-SH) to form acetyl CoA, concomitant with reduction of one molecule of NAD^+ to NADH. Further metabolism of acetyl CoA and NADH generates approximately an additional 28 molecules of ATP per glucose molecule oxidized.

Fermentation also occurs in animal cells, although lactic acid, rather than alcohol, is the product. During prolonged contraction of mammalian skeletal muscle cells — for example, during exercise — oxygen can become scarce within the muscle tissue. As a consequence, glucose catabolism is limited to glycolysis, and muscle cells convert two pyruvates to two molecules of lactic acid by a reduction reaction that also oxidizes two NADHs to two NAD^+s (Figure 12-5a, *right*). A monocarboxylic transporter can then transport the lactate out of the cell. Once it is secreted into the blood, some of the lactic acid passes into the liver, where it is reoxidized to pyruvate and either further metabolized to CO_2 aerobically or converted back to glucose. Much lactate is metabolized to CO_2 by the heart, which is highly perfused by blood and can continue aerobic metabolism at times when exercising, oxygen-poor skeletal muscles secrete lactate. If too much lactic acid accumulates in the blood, the acid causes an unhealthy decrease in the pH of the blood (lactic acidosis). Lactic acid bacteria (the organisms that spoil milk) and other prokaryotes also generate ATP by the fermentation of glucose to lactic acid.

Fermentation is a much less efficient way to generate ATP than aerobic oxidation and therefore occurs in animal cells only when oxygen is scarce. In the presence of oxygen, pyruvate formed by glycolysis is transported into mitochondria, where it is oxidized by O_2 to CO_2 and H_2O via the series of reactions outlined in Figure 12-5b. This aerobic metabolism of glucose, which occurs in stages II–IV of the process outlined in Figure 12-1, generates an estimated 28 additional ATP molecules per original glucose molecule, far outstripping the ATP yield from anaerobic glucose metabolism (fermentation).

To understand how ATP is generated so efficiently by aerobic oxidation, we must consider first the structure and function of the organelle responsible, the mitochondrion. The structure, dynamics, and functions of mitochondria are the subjects of the next two sections.

KEY CONCEPTS OF SECTION 12.2

First Step of Harvesting Energy from Glucose: Glycolysis

- In a process known as *aerobic oxidation*, cells convert the energy released by the oxidation of glucose or fatty acids into formation of the terminal phosphoanhydride bond of ATP.
- The complete aerobic oxidation of each molecule of glucose produces 6 molecules of CO_2 and approximately 30 ATP molecules. The entire process, which starts in the cytosol and is completed in the mitochondrion, can be divided into four stages: (I) degradation of glucose to pyruvate in the cytosol (glycolysis); (II) pyruvate oxidation to CO_2 in the mitochondrion coupled to generation of the high-energy electron carriers NADH and $FADH_2$ (via the citric acid cycle); (III) electron transport to generate a

proton-motive force together with conversion of molecular oxygen to water; and (IV) ATP synthesis (see Figure 12-1). From each glucose molecule, two ATPs are generated by stage I and approximately 28 from stages II–IV.

- In glycolysis (stage I), cytosolic enzymes convert glucose to two molecules of pyruvate and generate two molecules each of NADH and ATP (see Figure 12-3).
- The rate of glucose oxidation via glycolysis is regulated by the inhibition or stimulation of several enzymes, depending on the cell's need for ATP (see Figure 12-4). Glucose is stored, for example, as glycogen, when ATP is abundant.
- In the absence of oxygen (anaerobic conditions), cells can metabolize pyruvate to lactic acid or (in the case of yeast) to ethanol and CO_2, in the process of converting NADH back to NAD^+, which is necessary for continued glycolysis. In the presence of oxygen (aerobic conditions), pyruvate is transported into the mitochondrion, where it is metabolized to CO_2, in the process generating abundant ATP (see Figure 12-5).

12.3 The Structure of Mitochondria

Oxygen-producing photosynthetic cyanobacteria first appeared about 2.7 billion years ago. The subsequent buildup of oxygen in Earth's atmosphere during the next approximately 1 billion years opened the way for organisms to evolve the very efficient aerobic oxidation pathway, which in turn permitted the evolution, especially during what is called the *Cambrian explosion*, of large and complex body forms and associated metabolic activities. In eukaryotic cells, aerobic oxidation is carried out by mitochondria (stages II–IV in Figure 12-1). In effect, mitochondria are ATP-generating factories, taking full advantage of this plentiful oxygen. We first describe their structure, dynamics, and diverse functions that extend well beyond making ATP, and then the reactions they employ to degrade pyruvate and make ATP.

Mitochondria Are Abundant, Multifunctional Organelles

An individual mitochondrion (Figure 12-6a) is about the size of an *Escherichia coli* bacterium, which is not surprising because, as we shall see below, bacteria are thought to be the evolutionary precursors of mitochondria. Most eukaryotic cells contain many mitochondria, which may be fused to one another into large networks and may collectively occupy as much as 25 percent of the

volume of the cytoplasm. The numbers of mitochondria in a cell — hundreds to a few thousands in most mammalian cells, as many as half a million per cell in mammalian eggs — are typically regulated to match the cell's requirements for ATP (e.g., specialized stomach cells that use a lot of ATP for acid secretion have many mitochondria).

FIGURE 12-6 Internal structure of a mitochondrion. (a) Schematic diagram showing the principal mitochondrial membranes and compartments. The smooth outer membrane forms the outside boundary of the mitochondrion. The inner membrane is apparently a

single continuous membrane that has three distinct domains: boundary membrane, cristae, and crista junctions. The boundary membrane is flat and lies immediately below and adjacent to the outer membrane. The cristae are tubelike or flat, pancake-like invaginations that extend from the boundary membrane into the center of the mitochondrion. The sharp bends that form the connection between the boundary membrane and the cristae are called *crista junctions*. The intermembrane space is that fluid-filled space between the inner and outer membranes. The matrix is the fluid-filled space within the inner membrane (on the opposite side of the inner membrane from the intermembrane space). The ATP synthases (also called F_0F_1 *complexes*, small yellow spheres), which synthesize ATP, are aligned in rows as dimers at the bends in the cristae membrane (described later in Figure 12-34e) and protrude into the matrix. The matrix contains the mitochondrial DNA (blue strands), ribosomes (small blue spheres), and granules (large yellow spheres). (b) Transmission electron micrograph of a thin section of a human cell line — HeLa cells — showing a mitochondrion's inner and outer membranes with cristae in parallel, ladder-like stacks. One crista junction is highlighted with a white dotted circle. The ladder-like stacks of cristae can also be visualized using superresolution fluorescence microscopy (see Figure 12-8). (c) Computer-generated model of a section of a mitochondrion from chicken brain. This model is based on a three-dimensional electron microscopic image calculated from a series of two-dimensional electron micrographs (such as that in panel b) recorded at regular intervals. This technique is analogous to a three-dimensional x-ray tomogram or CAT scan used in medical imaging. Note the tightly packed cristae (yellow-green), the inner membrane (light blue), the outer membrane (dark blue) and the crista junction (white dotted circle). (d) Cristae and crista junctions from human fibroblasts were visualized and modeled using electron microscopy and tomography. The right panel shows one of the multiple sections through the mitochondrion imaged using transmission electron microscopy, with the mitochondrial membranes clearly distinguished. The sharp bends in the inner membrane at the crista junctions (dotted circles) that separate the crista membranes from the inner boundary membrane are seen clearly. The left panel shows a three-dimensional tomographic model of the laminar cristae seen edge on (green) and crista junctions (orange spheres) overlaid with the EM image.

USA* **110**:8936–8941, Fig. 6, Fig. 6A and C.]

Although our focus in this chapter is on the structure of mitochondria and the mechanisms by which they generate ATP, it is important to recognize that mitochondria participate in a wide variety of other critical cellular processes (Table 12-1). Mitochondria are involved with the biosynthesis of many small molecules. In several cases, some steps in these biosynthetic pathways take place within the mitochondria and some outside (extramitochondrial steps), requiring precursors and products to be shuttled into and out of the mitochondria via transport proteins. For example, in many eukaryotes, mitochondria host the first rate-limiting step in heme biosynthesis. The product of this first step is then exported for additional modification in the cytoplasm, producing an intermediate that must then be imported into the mitochondria for the terminal steps. The biosynthesis in the cytoplasm of a wide variety of small molecules depends on mitochondria. Mitochondria provide small organic molecules to the cytoplasm — for example, citrate, isocitrate, malate, formate, and α-ketoglutarate, that can be used to generate NADPH (an energy source), acetyl CoA (a carbon source), or other precursors for the extramitochondrial biosynthesis of molecules such as glutathione, purines, fatty acids, and cholesterol.

TABLE 12-1 • Multiple Functions of Mitochondria

Biosynthesis or processing of small molecules

Fatty acids
Steroid hormones
Pyrimidines
Iron-sulfur clusters
Heme
Phospholipids (phosphatidylethanolamine, phosphatidylglycerol, cardiolipin)
Ubiquinone
Amino acids (synthesis, interconversion, and catabolism)

Other mitochondrial functions
Oxidative phosphorylation and ATP synthesis Reactive oxygen species (ROS) homeostasis Ion homeostasis (e.g., calcium) Ammonia detoxification Fatty acid oxidation Thermogenesis (heat generation) in brown fat Contributions to innate immunity and inflammation Regulated cell death pathways (e.g., apoptosis)

Cellular processes influenced by mitochondrial-ER membrane contact sites (MCS)
Mitochondrial shape and dynamics (fusion, fission, autophagy) PINK1/Parkin-dependent mitophagy (initiated at MCSs) Calcium transport into mitochondria (see Figure 15-29) Calcium homeostasis and calcium-mediated signaling Glucose and energy metabolism Mitochondrial import from the ER of lipids, including phosphatidylserine and possibly cholesterol Mitochondrial biosynthesis of lipids, including phosphatidylethanolamine and steroid hormones Responses to stress Cell survival via regulated cell death (see Chapter 22) Inflammatory responses via the inflammasome and innate immune responses (see Chapter 24) Pathways implicated in viral infections (cytomegalovirus, hepatitis C virus) Neurodegenerative pathology (Alzheimer's and Parkinson's diseases)

Mitochondria Have Two Structurally and Functionally Distinct Membranes

The details of mitochondrial structure can be observed with electron microscopy (Figures 1-20 and 12-6) and superresolution fluorescence microscopy (Figure 12-8). Each mitochondrion has two distinct, concentric membranes: the **mitochondrial inner membrane** and **mitochondrial outer membrane**. The outer mitochondrial membrane defines the smooth outer perimeter. The inner mitochondrial membrane lies underneath the outer membrane. The inner mitochondrial membrane is a single continuous membrane that itself can be considered to have three compositionally and structurally distinct domains. The *boundary membrane* (or inner boundary membrane) is the flat inner mitochondrial membrane that lies immediately inside and adjacent to the outer membrane. The **mitochondrial cristae** are the numerous invaginations of the inner membrane that extend from the boundary membrane at the perimeter into the center of the mitochondrion. The invaginating cristae greatly expand the surface area of the inner mitochondrial membrane. As we shall see below, the cristae's membranes are the site of ATP synthesis — thus the invaginations increase the mitochondrion's capacity to generate ATP. The connection between the inner boundary membrane and a crista is called a *crista junction* (Figure 12-6).

The lengths of the cristae and their structures (which may be tubular in shape or flat and pancake-like) can vary within a mitochondrion. They tend to form stacks that in cross section look like the steps of a ladder (Figure 12-6b and c, also see Figures 1-21 and 12-8). There can be regions within the mitochondria that have densely stacked cristae and regions that have less dense cristae or are even devoid of cristae. The crista junctions and the edges and tips of the cristae are highly curved. The curvature of the crista junctions (see Figures 12-6 and 12-30e) is due to a protein complex called *MICOS* (*mi*tochondrial *co*ntact *s*ite and cristae organizing system), which has an integral membrane protein subunit that homo-oligomerizes and bends the inner membrane to produce high curvature. MICOS also mediates close juxtaposition of the outer membrane and inner membrane by binding to outer membrane–associated proteins. The binding partners for MICOS in the outer membrane include the Tom and SAM protein complexes (these complexes, discussed in Chapter 13, are involved in import of proteins into the mitochondria). MICOS is necessary to maintain normal structures of cristae in mitochondria. Additionally, MICOS appears to function as a diffusion barrier to prevent mixing of the distinct proteins and lipids in the boundary membrane and crista membranes. We will discuss the molecular basis of the curvature at the edges and tips of the cristae in Section 12.6.

The outer and inner membranes topologically define two fluid-filled submitochondrial compartments: the **mitochondrial**

intermembrane space, between the outer and inner membranes, and the **mitochondrial matrix**, or central compartment, which forms the lumen within the inner membrane (see Figure 12-6a). Many of the proteins directly involved with transforming the energy of nutrients into the energy stored in ATP, such as the proteins of the electron-transport chain and ATP synthase, are located in the inner mitochondrial membrane. In typical liver mitochondria, for example, the surface area of the inner membrane, including cristae, is about five times that of the outer membrane. In fact, the total area of all inner mitochondrial membranes in liver cells is about 17 times that of the plasma membranes. The mitochondria in heart and skeletal muscle contain three times as many cristae as are found in typical liver mitochondria — presumably reflecting the greater demand for ATP by muscle cells.

Over a thousand different types of polypeptides are required to make and maintain mitochondria and permit them to function. Defective functioning of mitochondria-associated proteins — due, for example, to inherited genetic mutations — leads to over 250 human diseases. The most common of these are electron-transport chain diseases, which result from mutations in any one of 150 genes and exhibit a very wide variety of clinical abnormalities affecting muscles, the heart, the nervous system, and the liver, among other physiological systems. Other mitochondria-associated diseases include Miller syndrome, which results in multiple anatomic malformations, and connective tissue defects.

The most abundant protein in the outer mitochondrial membrane is a mitochondrial β-barrel **porin** called *VDAC (v*oltage-*d*ependent *a*nion *c*hannel), a multifunctional transmembrane channel protein that is similar in structure to bacterial porins (see Figure 10-18). Ions and most small hydrophilic molecules (up to about 5000 Da) can readily pass through these channel proteins when they are open. Although there may be metabolic regulation of the opening of mitochondrial porins and thus of the flow of metabolites across the outer membrane, the inner membrane is the major permeability barrier between the cytosol and the mitochondrial matrix, controlling the rate of mitochondrion-mediated oxidation and ATP generation.

Proteins constitute 76 percent of the total mass of the inner mitochondrial membrane — a higher fraction than in any other cellular membrane. Many of these proteins are key participants in oxidative phosphorylation. They include ATP synthase, proteins responsible for electron transport, and a wide variety of transport proteins that permit the movement of metabolites between the cytosol (via the intermembrane space) and the mitochondrial matrix. The human genome encodes 48 members of one family of mitochondrial transport proteins. One of these, the ADP/ATP carrier, is an antiporter that moves newly synthesized ATP out of the matrix and into the inner membrane space (and subsequently the cytosol) in exchange for ADP originating from the cytosol. Without this essential antiporter, the energy trapped in the chemical bonds

of mitochondrial ATP made in the matrix would not be available to the rest of the cell.

Keep in mind that plants, as well as animals, have mitochondria and perform aerobic oxidation. In plants, stored carbohydrates, mostly in the form of starch, are hydrolyzed to glucose. Glycolysis then produces pyruvate that is transported into mitochondria, as in animal cells. Mitochondrial oxidation of pyruvate and concomitant formation of ATP occur in photosynthetic cells during dark periods when photosynthesis is not possible, and in roots and other non-photosynthetic tissues at all times. We will discuss photosynthesis in chloroplasts in Section 12.7.

The inner mitochondrial membrane and matrix are the sites of most reactions involved in the oxidation of pyruvate and fatty acids to CO_2 and H_2O and the coupled synthesis of ATP from ADP and P_i (see Figure 12-13). Each of these reactions occurs in a discrete membrane or space in the mitochondrion.

Mitochondria Contain DNA and Evolved from a Single Endosymbiotic Event Involving Alphaproteobacterium

Although the vast majority of DNA in most eukaryotes is found in the nucleus, some DNA is present within the mitochondria of

animals, plants, and fungi and within the chloroplasts of plants. Many lines of evidence indicate that mitochondria and chloroplasts evolved from bacteria that were engulfed into ancestral cells, forming **endosymbionts** (Figure 12-7). Over evolutionary time, most of the bacterial genes in the endosymbiont bacteria were lost from the organelles' DNA — some were lost because their function was replicated by nuclear-encoded genes and others were simply transferred to nuclear chromosomes. However, mitochondria and chloroplasts in today's eukaryotes retain DNA encoding several proteins essential for organelle function as well as the ribosomal and transfer RNAs required for the intramitochondrial and intrachloroplast synthesis of those proteins. Thus eukaryotic cells have multiple genetic systems: a predominant nuclear system and secondary systems with their own DNA, ribosomes (see Figure 3-49), and tRNAs in mitochondria and chloroplasts. As detailed in Chapter 13, the majority of proteins inside mitochondria and chloroplasts are encoded by nuclear DNA, synthesized on cytosolic ribosomes, and subsequently imported into the organelle.

FIGURE 12-7 Endosymbiont hypothesis for the evolutionary origin of mitochondria and chloroplasts. Endocytosis of a bacterium by an ancestral, precursor eukaryotic cell (step 1) would generate an organelle with two membranes, the outer membrane derived from the precursor's plasma membrane and the inner one from the bacterial membrane (step 2). There is uncertainty as to whether the ancestral cell already contained a nucleus (as shown here) or developed a nucleus concomitant with or subsequent to engulfing the bacterial precursor to the mitochondrion (left pathway). Proteins localized to the ancestral bacterial membrane would retain their orientation, such that the portion of the protein once facing the extracellular space would now face the intermembrane space. For example, the F_1 subunit of ATP synthase, localized to the cytosolic face of the bacterial membrane, would face the matrix of the evolving mitochondrion (*left*) or chloroplast (*right*). Budding of vesicles from the inner chloroplast membrane, such as occurs during development of chloroplasts in contemporary plants, would generate the thylakoid membranes with the F_1 subunit remaining on the cytosolic face, facing the chloroplast stroma (step 3). The organelle DNAs are indicated. Membrane surfaces facing a shaded area are cytosolic faces; surfaces facing an unshaded area are exoplasmic faces.

Analysis of mitochondrial DNA (mtDNA) sequences from multiple eukaryotes provides strong support for the idea that the mitochondrion had a single origin, most likely a bacterial symbiote whose closest contemporary relatives are alphaproteobacteria (also

called α purple, see Figure 1-1). Because these are obligate intracellular parasites, the ancestor of mitochondria may have had an intracellular lifestyle that facilitated its evolution into an intracellular symbiote.

In organisms whose mtDNA includes only a limited number of genes, the same set of mitochondrial genes is retained, regardless of the phyla that include these organisms. There are several hypotheses for why these genes were never successfully transferred to the nuclear genome: their encoded polypeptides are too hydrophobic to be imported from the cytosol by crossing the outer mitochondrial membrane, the large size of rRNAs may interfere with their import into mitochondria, and differential regulation of their expression in response to conditions within individual mitochondria may be advantageous. If these genes were located in the nucleus, it would be difficult to tailor the regulation of their expression to accommodate specifically the needs of only one or a few mitochondria whose status required an alteration in gene expression.

The Size, Structure, and Coding Capacity of mtDNA Vary Considerably Among Organisms

Surprisingly, the size of the mtDNA, the number and nature of the proteins it encodes, and even the mitochondrial genetic code itself can vary greatly between different organisms. The mtDNAs of most multicellular animals are approximately 16-kb circular molecules that encode intron-less genes compactly arranged on both DNA strands. Vertebrate mtDNAs encode the two rRNAs found in mitochondrial ribosomes, the 22 tRNAs used to translate mitochondrial mRNAs, and 13 proteins involved in electron transport and ATP synthesis. The smallest mitochondrial genomes in *Plasmodium*, intracellular parasites that cause malaria in humans (Figure 1-25) are only about 6 kb, encoding three proteins and the mitochondrial rRNAs.

Plant mitochondrial genomes are many times larger than those of metazoans, in part due to the presence of non-protein-coding introns, pseudogenes, mobile DNA elements, and pieces of foreign (chloroplast, nuclear, and viral) DNA, evidence of many DNA changes during evolution of these plants. For instance, *Arabidopsis thaliana*, a member of the mustard weed family, has 366 kb of mtDNA and cucurbit plants (e.g., melon and cucumber) have about 2 Mb of mtDNA.

Several proteins encoded by mtDNA in some species are encoded by nuclear DNA in other, closely related species. A striking example involves the *coxII* gene, which encodes subunit 2 of cytochrome *c* oxidase in the mitochondrial electron-transport chain (described in

detail below). This gene is found in mtDNA in all multicellular plants studied except for certain related species of legumes, including the mung bean and the soybean, in which the *coxII* gene is nuclear.

Most mtDNA encoded and intramitochondrially synthesized proteins identified thus far are subunits of multimeric complexes used in electron transport or ATP synthesis that we will describe shortly. Thus most of the mitochondrial proteome, such as those proteins involved in the processes listed in Table 12-1, are encoded by nuclear genes, synthesized on cytosolic ribosomes, and imported into the organelle by processes discussed in Chapter 13.

Mitochondrial DNA Is Located in the Matrix and Transferred During Mitosis to Daughter Cells by Cytoplasmic Inheritance

The mitochondrial DNA (mtDNA) is located in the mitochondrial matrix, and in the rapidly growing cells shown in Figure 12-8, the mtDNA is often seen in regions devoid of densely stacked cristae. Replication of mtDNA and division of the mitochondria can be followed in live cells using time-lapse microscopy. Such studies show that in most organisms, mtDNA replicates throughout interphase. At mitosis, each daughter cell receives approximately the same number of mitochondria from the cytoplasm of the

parental cell (a processed called *cytoplasmic inheritance*), but because there is no mechanism for apportioning exactly equal numbers of mitochondria to the daughter cells, some cells contain more mtDNA than others. If a mutation occurs in one mtDNA molecule in a cell, after cell division one daughter cell but not the other might inherit the mutant mtDNA molecule, but most of the mtDNA molecules in that cell would not carry the mutation. The total amount of mtDNA in a cell depends on the number of mitochondria, the size of the mtDNA molecules, and the number of mtDNA molecules per mitochondrion. Each of these parameters varies greatly between cell types. A typical human cell has about 1000–2000 mtDNA molecules; however, a human egg has about 500,000 mtDNA molecules, and a sperm has only about 100.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 12-8 Dual staining reveals multiple mitochondrial DNA molecules in the mitochondrial matrix. Live human HeLa cells expressing a fluorescently labeled mitochondrial inner membrane protein (COX8A) that preferentially localizes in the cristae were treated with the double-stranded DNA binding fluorescent dye PicoGreen and then examined using (a) confocal microscopy to visualized the stained mitochondrial DNA and (b) superresolution microscopy to visualize the inner/cristae membranes (COX8A fluorescence). White arrowheads and red arrows highlight regions in this single mitochondrion with either little or intense mtDNA staining, respectively, in panel (a), and corresponding regions with either relatively dense stacks of cristae or regions relatively devoid of cristae stacks in panel (b). In general, the mtDNA in the matrix was concentrated in regions relatively devoid of dense cristae stacks. (c) Merged image of DNA staining (red) and Cox8A fluorescence (inner/crista membrane, green).

[T. Stephan et al., 2019, "Live-Cell STED Nanoscopy of Mitochondrial Cristae." *Sci. Rep.* **9**:12419 (2019). https://doi.org/10.1038/s41598-019-48838-2.]

The dramatic difference in the amount of mtDNA per cell in eggs and sperm has a profound effect on the inheritance of mtDNA. In mammals and most other multicellular organisms, the sperm contributes little (if any) cytoplasm to the zygote, and virtually all the mitochondria in the embryo are derived from those in the egg, not the sperm. Studies in mice have shown that 99.99 percent of mtDNA is maternally inherited, but a small part (0.01 percent) is inherited from the male parent. In higher plants, mtDNA is inherited exclusively in a uniparental fashion through the female parent (egg), not the male (pollen).

Products of Mitochondrial Genes Are Not Exported

Most, if not all, RNA transcripts of mtDNA and their translation products remain in the mitochondrion in which they are produced, and all mtDNA-encoded proteins are synthesized on mitochondrial ribosomes. Mitochondrial DNA encodes the rRNAs of mitochondrial ribosomes, although most of the ribosomal proteins are imported from the cytosol. In animals and fungi, all the tRNAs used for protein synthesis in mitochondria are also encoded by mtDNAs. However, in plants and many protozoans, most mitochondrial tRNAs

are encoded by the nuclear DNA and imported into the mitochondrion.

The structure of the human mitochondrial ribosome is shown in Figure 3-49. Reflecting the bacterial ancestry of mitochondria, mitochondrial ribosomes resemble bacterial ribosomes and differ from eukaryotic cytosolic ribosomes in their RNA and protein compositions, their size, and their sensitivity to certain antibiotics (see Table 5-2). For instance, chloramphenicol blocks protein synthesis by bacterial and mitochondrial ribosomes from most organisms, but cycloheximide, which inhibits protein synthesis on eukaryotic cytosolic ribosomes, does not affect mitochondrial ribosomes. This sensitivity of mitochondrial ribosomes to the important aminoglycoside class of antibiotics, which includes chloramphenicol, is the main cause of the toxicity in patients that these antibiotics can cause. ■

Mitochondrial Genetic Codes Can Differ from the Standard Nuclear Code

The genetic code used in animal and fungal mitochondria is different from the standard code used in all prokaryotic, eukaryotic nuclear, and plant mitochondrial genes; remarkably, the code even differs among mitochondria from different species. Why and how these differences arose during evolution is a mystery. UGA, for

example, is normally a stop codon, but is read as tryptophan by human and fungal mitochondrial translation systems; AGA and AGG, the standard nuclear codons for arginine, also code for arginine in fungal and plant mtDNA, but they are stop codons in mammalian mtDNA and serine codons in *Drosophila* mtDNA.

Mutations in Mitochondrial DNA Cause Several Genetic Diseases in Humans

The severity of disease caused by a mutation in mtDNA depends on the nature of the mutation and on the proportion of mutant and wild-type mtDNAs present in a particular cell type. Generally when mutations in mtDNA are found, cells contain mixtures of wild-type and mutant mtDNAs — a condition known as *heteroplasmy*. Each time a mammalian somatic or germ-line cell divides, the mutant and wild-type mtDNAs segregate randomly into the daughter cells. Thus the mtDNA genotype, which fluctuates from one generation and from one cell division to the next, can drift toward predominantly wild-type or predominantly mutant mtDNAs. Since all enzymes required for the replication and growth of mammalian mitochondria, such as the mitochondrial DNA and RNA polymerases, are encoded in the nucleus and imported from the cytosol, a mutant mtDNA should not be at a replication disadvantage; mutants that have large deletions of mtDNA might even be at a selective advantage because they can replicate faster.

Recent research suggests that the accumulation of mutations in mtDNA is an important component of aging in mammals. Mutations in mtDNA have been observed to accumulate over time, probably because mammalian mtDNA is not repaired in response to DNA damage.

With few exceptions, all human cells have mitochondria, yet mutations in mtDNA affect only some tissues. Those most commonly affected are tissues that have a high requirement for the ATP produced by oxidative phosphorylation and tissues that require most or all of the mtDNA in the cell to synthesize sufficient amounts of functional mitochondrial proteins. For instance, *Leber's hereditary optic neuropathy* (degeneration of the optic nerve) is caused by a missense mutation in the mtDNA gene encoding subunit 4 of the NADH-CoQ reductase (complex I), a protein required for ATP production by mitochondria (see below). Several large deletions in mtDNA cause another set of diseases, including *chronic progressive external ophthalmoplegia*, characterized by eye defects, and *Kearns–Sayre syndrome*, characterized by eye defects, an abnormal heartbeat, and central nervous system degeneration. A third condition, causing "ragged-red" muscle fibers (with improperly assembled mitochondria) and associated uncontrolled jerky movements, is due to a single mutation in the TΨCG loop of the mitochondrial lysine tRNA. As a result of this mutation, the translation of several mitochondrial proteins is apparently inhibited. ■

KEY CONCEPTS OF SECTION 12.3

The Structure of Mitochondria

- In eukaryotic cells, mitochondria use aerobic oxidation to generate ATP. These multifunctional organelles are also responsible for many other key activities (see Table 12-1), including biosynthesis and metabolism of a wide variety of small molecules and regulated cell death.
- The mitochondrion has two distinct membranes (outer and inner) and two distinct subcompartments (the intermembrane space between the two membranes, and the matrix surrounded by the inner membrane) (see Figure 12-6). Aerobic oxidation occurs in the mitochondrial matrix and on the inner mitochondrial membrane.
- The inner mitochondrial membrane is a single continuous membrane with three compositionally, structurally, and functionally distinct domains: boundary membrane, cristae, and crista junctions.
- There are more than one thousand proteins associated with mammalian mitochondria, most of which are encoded by nuclear genes.
- Mitochondria and chloroplasts contain DNA that encodes a relatively small number of proteins involved in mitochondrial or photosynthetic electron transport and ATP synthesis (13 in mammalian mitochondria), ribosomal RNAs and sometimes tRNAs necessary to translate the organelle mRNAs.
- Mitochondrial DNA (mtDNA) and chloroplast DNA most likely evolved from bacteria that formed a symbiotic relationship with ancestral cells (see Figure 12-7).
- Most of the genes originally in the bacterial precursors to mitochondria and chloroplasts were either lost because their functions were redundant with nuclear genes or moved to the nuclear genome over evolutionary time, leaving different gene sets in the organelle DNAs of different organisms.
- Animal mtDNAs are circular molecules, reflecting their probable bacterial origin. Plant mtDNAs and chloroplast DNAs are generally longer than mtDNAs from other eukaryotes, largely because they contain more noncoding regions and repetitive sequences.
- Mitochondrial DNA (mtDNA) is located in the mitochondrial matrix and is often seen in regions devoid of densely stacked cristae.
- Because most mitochondrial DNA (mtDNA) is inherited from egg cells rather than sperm, mutations in mtDNA exhibit a maternal cytoplasmic pattern of inheritance. Similarly, chloroplast DNA is exclusively inherited from the maternal parent.

- Mitochondrial ribosomes resemble bacterial ribosomes in their structure and in their sensitivity to drugs such as chloramphenicol (sensitive) and cycloheximide (resistant).
- The genetic code of animal and fungal mtDNA differs slightly from that of bacterial and nuclear genomes and varies among different animals and fungi. In contrast, plant mtDNAs appear to conform to the standard genetic code.
- Several human neuromuscular disorders result from mutations in mtDNA. Patients generally have a mixture of wild-type and mutant mtDNA in their cells (heteroplasmy): the higher the fraction of mutant mtDNA, the more severe the mutant phenotype.

12.4 The Dynamics of Mitochondria and Mitochondrial-ER Membrane Contact Sites

Mitochondria are dynamic organelles that move about through the cytoplasm, merge with one another (fuse) to form large networks and break away from these networks (fission). Mitochondrial functions can be influenced by these dynamic behaviors and by the abilities of their outer membranes to attach to and interact with the plasma membrane and membranes of other organelles. Here we describe several features of mitochondrial dynamics and mitochondrial-endoplasmic reticulum (ER) membrane contact sites.

Mitochondria Are Dynamic Organelles

Many methods, including analysis of fluorescently labeled mitochondria in live cells, have been used to show that mitochondria are highly dynamic. They can move about the cell within the cytoplasm and undergo frequent **fusions** (merging) and **fissions** (breaking apart) that generate tubular, sometimes branched networks (Figures 12-9a and b) which may account for some of the wide variety of mitochondrial morphologies seen in different types of cells. Damaged or otherwise malfunctioning mitochondria can be recognized as such and consequently degraded as part of a quality control mechanism.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 12-9 Mitochondria undergo rapid fusion and fission. (a) A human HeLa cell labeled with a mitochondrion-specific fluorescent dye (MitoTracker Green) was imaged using three-dimensional structured illumination fluorescence microscopy (a 6.1-µm-thick section through the cell is shown). The network of fused and branched mitochondria is seen in the cytoplasm, with only a few mitochondria observed above or below the nucleus (outlined by thin gray dashed line). The identity of the striations seen within the mitochondria in this image is not known. The mitochondria are shown in artificial colors to indicate their positions relative to the surface to which the cell is attached (blue is closest to and red farthest from the surface). (b) Mitochondria labeled with a fluorescent protein in a live normal mouse embryonic fibroblast were observed using time-lapse

fluorescence microscopy. Several mitochondria undergoing fusion (*top*) or fission (*bottom*) are artificially highlighted in blue and with arrows. (c) Mitochondrial fusion (*top*) and fission (*bottom*) are mediated by a set of GTPase enzymes (MFN1, MFN2, OPA1, and DRP1). The integral membrane proteins MFN1 and MFN2 $(\mathrm{MFN1/2})$ mediate outer mitochondrial membrane (OMM) fusion, which is followed by fusion of the inner mitochondrial membranes (IMM) mediated by the integral membrane protein OPA1. The matrix and inner membrane space (IMS) remain distinct. The soluble cytosolic GTPase DRP1 is recruited to a constricted site on the surface of a mitochondrion, where DRP1 polymers sever the membrane, resulting in fission. A variety of post-translational modifications of DRP1 regulate fission. (d) *Left*: Rat liver cells (hepatocytes) one day after being removed from the liver and placed in cell culture, are stressed and depolarized (lack some of the morphological and biochemical properties of epithelial cells; see Chapter 20), have low levels of oxidative phosphorylation and ATP production, and have fragmented mitochondria (visualized by staining with MitoTracker Green). *Right*: After growth in culture for 6 days, the hepatocytes become polarized, their mitochondria fuse, forming an extensive network, and the cells exhibit high levels of oxidative phosphorylation and ATP production. Insets show higher magnification views of the mitochondria.

Intracellular Mitochondrial Movements

Intracellular movement helps to establish the proper geographical distribution of mitochondria within cells. As we shall see below,

cells require that activities of mitochondria and other structures, including other organelles, must be coordinated. For example, in neurons (see Chapter 23) that have extensions called *axons* that can be centimeters to even a meter long, mitochondria must be transported from the region near the nucleus (cell body) to the ends of the axon where contact is made with other neurons to provide energy (ATP) and to regulate calcium levels (see below and Chapter 15). Proteins on the cytoplasmic surface of the outer mitochondrial membrane mediate mitochondrial interactions with motor proteins such as kinesin (Chapter 18) that drive intracytoplasmic movement via microtubules (Figure 18-28), including long distance movement through the axons of neurons. One such protein is called *Miro*, a GTPase that has calcium binding EF hands (Figure 3-7) that appear to confer calcium sensitivity to mitochondrial movement. Miro indirectly links mitochondria to kinesin, and it also is associated with MICOS in the inner membrane and thus influences cristae structure and function. Miro has also been implicated in mitochondrial-endoplasmic reticulum interactions and in Parkinson's disease, both described below. In addition to intracellular movement, mtDNA, and indeed intact mitochondria, have reported to be transferred from one cell to another via membrane tubules called *tunneling nanotubes*, which are described in Chapter 20.

Mitochondrial Fusion and Fission

When individual mitochondria fuse, each of the two membranes fuses (inner with inner, and outer with outer) and each of their distinct compartments intermix (matrix with matrix, intermembrane space with intermembrane space). A set of four evolutionarily conserved GTP-hydrolyzing (GTPase) enzymes — MFN1 (mitofusin 1), MFN2 (mitofusin 2), OPA1, and DRP1 — plays critical roles in mediating these membrane fusions and fissions (Figure 12-9c). These enzymes are members of the dynamin family of GTPases. Dynamin, the first-identified member of this family, mediates a comparable membrane fission reaction required during the pinching off of endocytic vesicles from the plasma membrane (see Chapter 14). Mutations in several of the genes encoding these GTPases can disrupt mitochondrial functions, such as maintenance of proper inner membrane structure and electric potential, the function of which is described in Section 12.6. These mutations result in truncated or enlarged mitochondria and can cause human disease. The inherited, autosomal dominant neuromuscular disease Charcot-Marie-Tooth subtype 2A is caused by loss-of-function mutations in MFN2 that lead to defects in peripheral nerve function and progressive muscle weakness, mainly in the feet and hands. Mutations in OPA1 are associated with autosomal dominant optic atrophy that influences nerves in the eye's retina.

What is the value of mitochondrial fission and fusion? It has been suggested that fusion helps to maintain a relatively homogeneous population of mitochondria within a cell. Should some subset of individual mitochondria suffer deleterious modification or loss of

important components, fusion with other mitochondria would permit restoration by sharing of those components. Studies of cells and organisms with mutations in genes encoding the fusion machinery suggest that fusion also plays a role in the proper localization of mitochondria within cells, maintaining the proper morphology and cristal organization, distribution of mitochondrial DNA, and maintenance of fully functional electron transport.

A number of functions are served by mitochondrial fission. For example, mitochondrial fission is particularly active when cells divide (particularly during the G_2 and M phases of the cell cycle; see Chapter 19). As a consequence, the multiple discrete mitochondria generated by fission are readily distributed into both daughter cells. In addition, fission provides a powerful mechanism of quality control by culling defective segments of mitochondria from the interconnected, healthy mitochondrial network. Should a portion of a large mitochondrial network become damaged or dysfunctional — for example, by the generation of high levels of reactive oxygen species (discussed later) or by mutations in the mitochondrial DNA — fission can separate the compromised segments from healthy segments.

Mitophagy Provides Mitochondrial Quality Control

Cells have the capacity to recognize damaged or dysfunctional segments of the mitochondrial network and, after they detach from

the network, can surround them with a membrane and then deliver them to lysosomes for degradation. This destruction of mitochondria, which is called **mitophagy** ("eating mitochondria"), is a subset of the general process called *autophagy* ("self eating") by which cells engulf in membranes and degrade organelles and portions of the cytosol (see Chapter 14). For example, when the environment of a cell has inadequate oxygen (hypoxia), enzymatic modification of proteins on the outer mitochondrial membrane induces mitophagy.

Hereditary early onset Parkinson's disease is caused by mutations in two gene encoding proteins that can mediate mitophagy. The proteins are PINK1 (a kinase) and Parkin (an E3 ubiquitin ligase that ubiquitinylates a substrate protein, thus targeting it for destruction by proteasomes; see Chapter 3). In healthy mitochondria, PINK1 resides in the mitochondrial matrix. In damaged or dysfunctional mitochondria, PINK1 resides on the outer mitochondrial membrane, where it recruits cytosolic Parkin. The Parkin is activated and polyubiquitinylates outer membrane proteins, thus targeting them for degradation and inducing mitophagy. There also are PINK1/Parkin-independent mechanisms that mediate mitophagy. Some studies suggest that mitochondrial stress (due to aging, pathogens, etc.) can induce inflammation and contribute to pathology and that mitophagy may mitigate mitochondrial stress-induced inflammation by removing defective segments of mitochondria. ■

Mitochondrial dynamism has additional features that are worth mentioning. Mitochondrial structure and function can change in response to the metabolic state of the cells. For example, the isolation of rat liver cells (hepatocytes) from the body and their transfer into cell culture stresses the cells and results in their depolarization (loss of some of their epithelial cell properties; see Chapter 20). These cells exhibit fragmentation of their mitochondria (Figure 12-9d, *left*) accompanied by low generation of ATP via oxidative phosphorylation. As the cells adjust to growth in cell culture, they become polarized (have a morphology and biochemistry more like that of hepatocytes in a liver), increase mitochondrial generation of ATP via oxidative phosphorylation, and exhibit an extensive network of fused mitochondria (Figure 12-9d, *right*).

Mitochondrial Function and Dynamics Can Depend on Direct Contacts with Other Organelles

The activities of mitochondria and other organelles must be coordinated with one another for efficient and effective cell function. Such coordination requires inter-organelle communication, including transfer of ions, small molecules, and macromolecules between organelles. Four mechanisms for such transfers include: release into the cytosol and organelle uptake of

ions and small molecules by transporters, pumps, and channels (Chapter 11); transfer of proteins across organelle membranes via pore-like integral membrane proteins (Chapter 13); transport via small membrane vesicles (Chapter 14); and direct, protein-mediated organelle-organelle binding via **membrane contact sites (MCSs)**. Mitochondria establish MCSs with many other organelles, including the endoplasmic reticulum (ER), lysosomes (vacuoles in yeast), peroxisomes, the plasma membrane, the Golgi, endosomes, and even lipid droplets (Chapter 10). Here we will focus on mitochondrial-ER MCSs. The portions of the ER membranes that form special contact regions with the mitochondria are called **mitochondria-associated membranes**, or **MAMs**.

Mitochondrial-ER MCSs can be visualized using electron microscopy and fluorescence microscopy (Figure 12-10). The MAMs' lipid and protein composition differs somewhat from that of the rest of the ER. At the MCSs, tethering proteins hold the MAM and the outer mitochondrial membrane about 10–30 nm apart. Those tethering proteins in yeast have been identified as a protein complex called *ERMES*. Mammals do not have the ERMES complex; they use what appears to be a variety of other proteins to tether mitochondria to the ER (see Figure 15-29).

EXPERIMENTAL FIGURE 12-10 At mitochondrial-ER membrane contact sites (MCSs) specialized regions of the endoplasmic reticulum called *mitochondria-associated membranes (MAMs)* directly contact mitochondria and influence mitochondrial shape, function, and sites of fission. (a) Three-dimensional model of a segment of a mitochondrion (red, only outer membrane shown) and the adjacent ER (yellow) determined from a line of cultured avian lymphoma cells using EM tomography (assembly of a three-dimensional image from consecutive individual sections). At the MCS, the MAM is the portion of the ER membrane that is closely apposed (10–30 nm distance) to the outer mitochondrial membrane. The regions of the MCSs are indicated by brackets. (b) A three-dimensional model of a mitochondrion (red) and adjacent MAMs (green) from a yeast cell using EM tomography. The two MAM domains are derived from ER tubules that in some cases can wrap around the mitochondrion, in the top case forming a clamp-like structure at the MCS that appears to constrict the mitochondrion in preparation for fission. (c) Many mitochondrial fission events occur at the mitochondrial-ER MCSs. These live-cell fluorescence microscopic images of a Cos-7 monkey cell show such a fission event observed

over the 8 seconds of imaging. We see mitochondria (green) and tubular ER (magenta) in a single field of view at 4-second intervals, visualized using a superresolution (97 nm) and high-speed method called *grazing incidence-structured illumination microscopy*. The arrows in the upper panel point to sites of constriction in the mitochondria at MCSs that will develop into sites of DRP1-mediated fission. The upper panel shows the cell at 0 seconds and the area outlined by a white dashed box is shown in the lower panels at three times (0, 4, and 8 seconds), which illustrate the rapid fission (white brackets indicate separation of the released mitochondrial ends) initiated at the MCS (white dotted oval in the left panel). To visualize the mitochondria and ER, the Cos-7 cells were transfected with cDNA vectors encoding two fluorescent proteins that specifically accumulate in either the outer mitochondrial membranes (mEmerald-Tomm20) or the lumen of the ER (mCherry-KDEL).

Mitochondrial-ER MCSs significantly contribute to many cellular processes (see Table 12-1). For example, these MCSs play important roles in mitochondrial dynamics. A majority of mitochondrial fission events occur at the mitochondrial-ER MCSs, although most of the MCSs are not associated with sites of fission. MCSs apparently initiate mitochondrial constriction by inducing an increased local density of filamentous actin polymers that, with the aid of myosin motor proteins, contract (Chapter 17). The contractions squeeze down on and thus constrict the mitochondrion. The change of shape of the mitochondrial outer membrane at the constriction recruits

DPR1, which completes membrane fission (see Figure 12-9c). In yeast, MAM tubules have been seen to loop completely around mitochondria (Figure 12-10b). In mammalian cells, the MAMs contact the mitochondria at fission sites, but they usually do not appear to loop fully around the mitochondria (Figure 12-10c).

MCSs also serve as interfaces for the transfer of ions (e.g., Ca^{2+}) and small molecules (e.g., glycerophospholipids) between the ER and mitochondria. These MCSs play an integral role in intracellular calcium and energy metabolism. Variations in the concentrations of calcium ions in intracellular compartments — cytosolic calcium ($[Ca^{2+}]_c$), mitochondrial calcium ($[Ca^{2+}]_m$), and calcium in the ER ($[Ca^{2+}]_{er}$) — are employed to control a wide variety of activities within cells, a process called *calcium signaling* (see Chapter 15). Calcium is also important for extracellular processes, such as the activity of some blood-clotting proteins. Intramitochondrial calcium ions play an important role in controlling mitochondrial function, and MCSs mediate this control by delivering calcium from the ER to mitochondria. For example, an increase in $[Ca^{2+}]_m$ in the matrix can increase mitochondrial production of ATP. Increased $[Ca^{2+}]_m$ directly increases the activities of three mitochondrial enzymes that produce NADH from NAD^+: pyruvate dehydrogenase (see Figure 12-5), and α-ketoglutarate and isocitrate dehydrogenases (see Figure 12-13 in the following section). As we shall see later in this chapter, NADH provides high-energy electrons for ATP synthesis. Thus continuous low-level release of Ca^{2+} from ER MAMs into

mitochondria is necessary for ATP synthesis when cells are in a basal, or resting, state. Increased delivery of Ca^{2+} via MCSs can occur when cells require more ATP — for example, when muscle cells are stimulated to contract. Strikingly, calcium signaling is used both to induce muscle contraction (see Chapter 17) and coordinately to increase mitochondrial ATP synthesis to provide the energy to fuel that contraction. When $[Ca^{2+}]_m$ is elevated, mitophagy can be induced. Indeed, mitochondrial calcium overload can activate regulated cell death pathways (Chapter 22). Thus the control of $[Ca^{2+}]_m$ can literally control the life and death of cells.

KEY CONCEPTS OF SECTION 12.4

The Dynamics and Functions of Mitochondria

- Mitochondria are dynamic organelles, undergoing intracellular transport, as well as fusion and fission reactions that are regulated by the state of the cell. In many cells, the fused mitochondria form a large, interconnected branched tubular network. A family of GTPases mediate mitochondrial membrane fusion and fission (see Figure 12-9). Mutations in the genes encoding some of these GTPases cause human diseases.
- Mitochondrial fission and fusion are thought to play roles in maintaining a relatively homogeneous population of mitochondria, distributing mitochondria among the daughter cells during cell division, and establishing a system of quality control to permit culling of defective mitochondria from healthy mitochondria.
- Defective mitochondria or segments of mitochondria are destroyed by a processed called *mitophagy*. Two proteins that can mediate mitophagy, PINK1 and Parkin, are encoded by genes that, when mutated, can be responsible for hereditary early onset Parkinson's disease.
- Membrane contact sites (MCSs) are regions of organelles that directly bind to one another via tethering proteins. Mitochondria form MCSs with many different organelles.
- Mitochondrial-endoplasmic reticulum (ER) MCSs significantly influences many cellular functions, including mitochondrial shape and dynamics (see Table 12-1). The portions

of the ER membranes that are in contact with mitochondria at MCSs are called *mitochondria-associated membranes (MAMs)* (see Figure 12-10).

- A majority of mitochondrial fission events occur at the mitochondrial-ER MCSs, although most of the MCS are not associated with sites of fission.
- MCSs also serve as interfaces for the transfer of ions (e.g., Ca^{2+}) and small molecules (e.g., glycerophospholipids) between the ER and mitochondria. These MCSs play an integral role in intracellular calcium and energy metabolism. Calcium influx into mitochondria from MAMs can stimulate ATP synthesis and, in the context of mitochondrial calcium overload, initiates a program of regulated cell death.

12.5 The Citric Acid Cycle and Fatty Acid Oxidation

We now continue our detailed discussion of glucose oxidation and ATP generation, exploring what happens to the pyruvate generated during glycolysis (stage I, see Figures 12-1 and 12-3) after it is transported into the mitochondrial matrix. The last three of the four stages of glucose oxidation (Figure 12-11) are:

- **Stage II:** Stage II can be subdivided into two distinct parts: (1) the conversion of pyruvate to acetyl CoA and CO_2, followed by (2) oxidation of acetyl CoA to CO_2 in the citric acid cycle. These oxidations are coupled to reduction of NAD^+ to NADH and of FAD to $FADH_2$. These two carriers can be considered the sources of high-energy electrons. (Fatty acid oxidation follows a similar route, with conversion of fatty acyl CoA to acetyl CoA.) Most of the reactions occur in or on the inner membrane facing the matrix.
- **Stage III:** Electron transfer from NADH and $FADH_2$ to O_2 via an electron-transport chain within the inner membrane converts the energy carried in those electrons into an electrochemical gradient across that membrane, called the *proton-motive force*.
- **Stage IV:** The energy of the proton-motive force is harnessed for ATP synthesis in the inner mitochondrial membrane. Stages III and IV together are called *oxidative phosphorylation*.

In the First Part of Stage II, Pyruvate Is Converted to Acetyl CoA and High-Energy Electrons

Within the mitochondrial matrix, pyruvate reacts with coenzyme A, forming CO_2, acetyl CoA, and NADH (see Figure 12-11, stage II). This reaction, catalyzed by *pyruvate dehydrogenase*, is highly exergonic ($\Delta G^{\circ\prime} = -8.0\,\text{kcal/mol}$) and essentially irreversible. Influx of calcium into the mitochondria at mitochondrial-ER MCSs (from the ER MAM) increases the activity of pyruvate dehydrogenase, driving the formation of acetyl CoA.

FIGURE 12-11 Summary of aerobic oxidation of glucose and fatty acids. Stage I: In the cytosol, glucose is converted to pyruvate (glycolysis) and fatty acid to fatty acyl CoA.

Pyruvate and fatty acyl CoA then move into the mitochondrion. Mitochondrial porins make the outer membrane permeable to these metabolites, but specific pyruvate and fatty acid transport proteins (yellow and blue colored ovals, respectively) in the inner membrane are required to import these molecules into the matrix. Fatty acyl groups are transferred from fatty acyl CoA to an intermediate carrier, transported across the inner membrane, and then reattached to CoA on the matrix side. **Stage II:** In the mitochondrial matrix, pyruvate and fatty acyl CoA are converted to acetyl CoA and then oxidized, releasing CO_2. Pyruvate is converted to acetyl CoA with the formation of NADH and CO_2; two carbons from fatty acyl CoA are converted to acetyl CoA with the formation of $FADH_2$ and NADH. Oxidation of acetyl CoA in the citric acid cycle generates NADH and $FADH_2$, GTP, and CO_2. **Stage III:** Electron transport reduces O_2 to H_2O and generates a proton-motive force. Electrons (blue) from reduced coenzymes NADH and $FADH_2$, are transferred via electron-transport complexes (colored shapes) to O_2 concomitant with transport of H^+ ions (red) from the matrix to the intermembrane space, generating the proton-motive force. Electrons from NADH flow from complex I (blue) to complex III (orange), bypassing complex II (yellow). Electrons from succinate flow through $FAD/FADH_2$ within complex II to complex III (orange), bypassing complex I. **Stage IV:** ATP synthase, also called the F_0F_1 *complex* (orange), harnesses the proton-motive force to synthesize ATP in the matrix. Antiporter proteins (purple and green ovals) transport ADP and P_i into the matrix and export hydroxyl groups and ATP. NADH generated in the cytosol is not transported directly to the matrix because the inner membrane is impermeable to NAD^+ and NADH; instead, a shuttle system (red) transports electrons from cytosolic NADH to NAD^+ in the matrix. O_2 diffuses into the matrix, and CO_2 diffuses out.

Acetyl CoA is a molecule that consists of a two-carbon acetyl group covalently linked to a longer molecule known as *coenzyme A (CoA)* (Figure 12-12). It plays a central role in the oxidation of pyruvate, fatty acids, and amino acids. In addition, it is an intermediate in numerous biosynthetic reactions, including the transfer of an acetyl group to histones (Figure 8-33) and many other mammalian proteins, and the synthesis of lipids such as cholesterol (Figure 10-26). In respiring mitochondria, however, the two-carbon acetyl

group of acetyl CoA is almost always oxidized to CO_2 via the citric acid cycle. Note that the two carbons in the acetyl group come from pyruvate; the third carbon of pyruvate is released as carbon dioxide.

FIGURE 12-12 The structure of acetyl CoA. This compound, consisting of an acetyl group covalently linked to a coenzyme A (CoA) molecule, is an important intermediate in the aerobic oxidation of pyruvate, fatty acids, and many amino acids. It also contributes acetyl groups to many biosynthetic pathways.

In the Second Part of Stage II, the Citric Acid Cycle Oxidizes the Acetyl Group in Acetyl CoA to CO_2 and Generates High-Energy Electrons

Nine sequential reactions operate in a cycle to oxidize the acetyl group of acetyl CoA to CO_2 (see Figures 12-11 and 12-13, stage II). This cycle is referred to by several names: the **citric acid cycle**, the *tricarboxylic acid (TCA) cycle*, and the *Krebs cycle*. The net result is that for each acetyl group entering the cycle as acetyl CoA, two molecules of CO_2, three of NADH, and one each of $FADH_2$ and GTP are produced. NADH and $FADH_2$ are high-energy electron carriers

that will play a major role in stage III of mitochondrial oxidation: electron transport.

As shown in Figure 12-13, the cycle begins with condensation of the two-carbon acetyl group from acetyl CoA and the four-carbon molecule *oxaloacetate* (step **1**) to yield the six-carbon *citric acid* (*citrate* when ionized, hence the name *citric acid cycle*). Reactions step **4** and step **5** each release a CO_2 molecule and reduce NAD^+ to NADH. The source of the oxygen for generating the CO_2 molecules in these reactions is water (H_2O), not molecular oxygen (O_2), and the enzymatic activities of the enzymes catalyzing reactions step **4** and step **5** are increased by the influx of calcium into the mitochondrion from the ER's MAM. Reduction of NAD^+ to NADH occurs during reaction step **9**; thus three NADHs are generated per turn of the cycle. In reaction step **7**, two electrons and two protons are transferred to FAD, yielding the reduced form of this coenzyme, $FADH_2$. Reaction step **7** is distinctive not only because it is an intrinsic part of the citric acid cycle (stage II) but also because it is catalyzed by a membrane-attached enzyme that, as we shall see, also plays an important role in stage III. In reaction step **6**, hydrolysis of the high-energy thioester bond in succinyl CoA is coupled to synthesis of one GTP by substrate-level phosphorylation. Because GTP and ATP are interconvertible,

$$\mathrm{GTP} + \mathrm{ADP} \rightleftharpoons \mathrm{GDP} + \mathrm{ATP}$$

this can be considered an ATP-generating step. Reaction step **9** regenerates oxaloacetate, so the cycle can begin again. Note that molecular O_2 does not participate in the citric acid cycle.

FIGURE 12-13 The citric acid cycle. Acetyl CoA is metabolized to CO_2 and the high-energy electron carriers NADH and $FADH_2$. In reaction **1**, a two-carbon acetyl residue from acetyl CoA condenses with the four-carbon molecule oxaloacetate to form the six-carbon citrate. In the remaining reactions (**2–9**), each molecule of citrate is eventually converted back to oxaloacetate, losing two CO_2 molecules in the process. In each turn of the cycle, four pairs of electrons are removed from carbon atoms, forming three molecules of NADH from three of NAD^+, one molecule of $FADH_2$ from FAD, and one molecule of GTP, from GDP and P_i. The two carbon atoms that enter the cycle with acetyl CoA are highlighted in blue through succinyl CoA. In succinate and fumarate, which are symmetric molecules, they can no longer be specifically denoted. Isotope-labeling studies have shown that these carbon atoms are *not* lost in the turn of the cycle in which they enter; on average, one will be lost as CO_2 during the next turn of the cycle and the other in subsequent turns.

Most enzymes and small molecules involved in the citric acid cycle are soluble in the aqueous mitochondrial matrix. These include CoA, acetyl CoA, succinyl CoA, NAD^+, and NADH, as well as most of the citric acid cycle enzymes. *Succinate dehydrogenase* (reaction step **7**), however, is a component of an integral membrane protein in the inner membrane, with its active site facing the matrix. The non-membrane-bound enzymes of the citric acid cycle can be isolated as very large **multiprotein complexes**. It is believed that within such complexes, the reaction product of one enzyme passes directly to the next enzyme without diffusing through the solution (see Figure 3-31).

Because glycolysis of one glucose molecule generates 2 pyruvate molecules, and thus 2 acetyl CoA molecules, the reactions in the glycolytic pathway and citric acid cycle produce 6 CO_2 molecules, 10 NADH molecules, and 2 $FADH_2$ molecules per glucose molecule (Table 12-3). Although these reactions also generate four high-energy phosphoanhydride bonds in the form of 2 ATP and 2 GTP molecules, this represents only a small fraction of the available energy released in the complete aerobic oxidation of glucose. The remaining energy is stored as high-energy electrons in the reduced coenzymes NADH and $FADH_2$, which can be thought of as high-energy electron carriers. The goal of stages III and IV is to recover this energy in the form of ATP.

TABLE 12-3 • Electron-Carrying Prosthetic Groups in the Electron-

Transport Chain

Protein Component	Prosthetic Groups[i]
NADH-CoQ reductase (complex I)	*FMN* Fe-S
Succinate-CoQ reductase (complex II)	FAD Fe-S

Transporters in the Inner Mitochondrial Membrane Help Maintain Appropriate Cytosolic and

Matrix Concentrations of NAD^+ and NADH

In the cytosol, NAD^+ is required for step **6** of glycolysis (see Figure 12-3); in the mitochondrial matrix, NAD^+ is required for the conversion of pyruvate to acetyl CoA and for three steps in the citric acid cycle (step **4**, step **5**, and step **9** in Figure 12-13). In each case, NADH is a product of the reaction. If glycolysis and oxidation of pyruvate are to continue, NAD^+ must be regenerated by oxidation of NADH to ensure that this substrate is available. (Similarly, the $FADH_2$ generated in stage II reactions must be reoxidized to FAD if FAD-dependent reactions are to continue.) As we will see in the next section (Section 12.6), the electron-transport chain *within* the inner mitochondrial membrane converts NADH to NAD^+ and $FADH_2$ to FAD as it reduces O_2 to water and converts the energy stored in the high-energy electrons in the reduced forms of these molecules into a proton-motive force (stage III). Even though O_2 is not involved in any reaction of the citric acid cycle, in the absence of O_2 this cycle soon stops operating because in such anaerobic conditions, the mitochondria cannot regenerate the required NAD^+ and FAD substrates. NAD^+ and FAD concentrations dwindle due to the inability of the electron-transport chain within the mitochondrion to oxidize NADH and $FADH_2$. These observations raise the question of how a supply of NAD^+ in the cytosol is regenerated.

If the NADH from the cytosol could move into the mitochondrial matrix and be oxidized by the electron-transport chain, and if the NAD^+ product could be transported back into the cytosol, regeneration of cytosolic NAD^+ would be simple when O_2 is available. However, the inner mitochondrial membrane is impermeable to NADH. To bypass this problem and permit the electrons from cytosolic NADH to be transferred *indirectly* to O_2 via the mitochondrial electron-transport chain, cells use several *electron shuttles* to transfer electrons from NADH in the cytoplasm to NAD^+ in the matrix. The operation of the most widespread shuttle — the *malate-aspartate shuttle* — is depicted in Figure 12-14.

FIGURE 12-14 The malate-aspartate shuttle. This cyclical series of reactions transfers electrons from NADH in the cytosol (via the intermembrane space) across the inner mitochondrial membrane, which is impermeable to NADH itself, to NAD^+ in the matrix. The net result is the replacement of cytosolic NADH with NAD^+ and matrix NAD^+ with NADH. Step **1**: Cytosolic malate dehydrogenase transfers electrons from cytosolic NADH to oxaloacetate, forming malate and NAD^+. Step **2**: An antiporter (blue oval) in the inner mitochondrial membrane transports malate into the matrix in exchange for α-ketoglutarate. Step **3**: Mitochondrial malate dehydrogenase converts malate back to oxaloacetate,

reducing NAD^+ in the matrix to NADH in the process. Step 4: Oxaloacetate, which cannot directly cross the inner membrane, is converted to aspartate by addition of an amino group from glutamate. In this transaminase-catalyzed reaction in the matrix, glutamate is converted to α-ketoglutarate. Step 5: A second antiporter (red oval) exports aspartate to the cytosol in exchange for glutamate. Step 6: A cytosolic transaminase converts aspartate to oxaloacetate and α-ketoglutarate to glutamate, completing the cycle. The blue arrows reflect the movement of the α-ketoglutarate, the red arrows the movement of glutamate, and the black arrows that of $\mathrm{aspartate/malate}$. It is noteworthy that as aspartate and malate cycle clockwise, glutamate and α-ketoglutarate cycle in the opposite direction.

For every complete cycle of the shuttle, there is no overall change in the numbers of NADH and NAD^+ molecules or the intermediates aspartate or malate. In the cytosol, however, NADH is oxidized to NAD^+, which can be used for glycolysis, and in the matrix, NAD^+ is reduced to NADH, which can be used for electron transport:

$$\mathrm{NADH_{cytosol}} + \mathrm{NAD^+{}_{matrix}} \rightarrow \mathrm{NAD^+{}_{cytosol}} + \mathrm{NADH_{matrix}}$$

Mitochondrial Oxidation of Fatty Acids Generates ATP

Up to now, we have focused mainly on the oxidation of carbohydrates, namely glucose, for ATP generation. Fatty acids are another important source of cellular energy. Cells can take up either glucose or fatty acids from the extracellular space with the help of specific transporter proteins (see Chapter 11). Should a cell not need to burn these molecules immediately, it can store them as a polymer

of glucose called *glycogen*, especially in muscle or liver, or as a trimer of fatty acids covalently linked to glycerol, called a **triacylglycerol** or **triglyceride**:

In some cells, excess glucose is converted into fatty acids and then triacylglycerols for storage. However, unlike microorganisms, animals are unable to convert fatty acids to glucose. When the cells need to burn these energy stores to make ATP (e.g., when a resting muscle begins to do work and needs to burn glucose or fatty acids as fuel), enzymes break down glycogen to glucose or hydrolyze triacylglycerols to fatty acids, which are then oxidized to generate ATP.

Fatty acids are the major energy source for some tissues, particularly adult heart muscle. In humans, in fact, more ATP is generated by the oxidation of 1 g of fats than by the oxidation of 1 g

of glucose. The oxidation of 1 g of triacylglycerol to CO_2 generates about six times as much ATP as does the oxidation of 1 g of hydrated glycogen. Thus considering the mass of stored fuel an organism must carry, triglycerides are more efficient than carbohydrates for storage of energy, in part because they are stored in anhydrous form and can yield more energy when oxidized, and in part because they are intrinsically more reduced (have more hydrogens) than carbohydrates. In mammals, the primary site of storage of triacylglycerol is fat (adipose) tissue, whereas the primary sites for glycogen storage are muscle and the liver. In animals, when tissues need to generate a lot of ATP, as in exercising muscle, signals are sent to adipose tissue to hydrolyze triacylglycerols and to release the fatty acids into the circulatory system so that they can move to and be transported into the ATPrequiring tissues.

Just as there are four stages in the oxidation of glucose, there are four stages in the oxidation of fatty acids. To optimize the efficiency of ATP generation, part of stage II (citric acid cycle oxidation of acetyl CoA) and all of stages III and IV of fatty acid oxidation are identical to those of glucose oxidation. The differences lie in cytosolic stage I and in the first part of mitochondrial stage II. In stage I, fatty acids are converted to a fatty acyl CoA in the cytosol in a reaction coupled to the hydrolysis of ATP to AMP and PP_i (inorganic pyrophosphate) (see Figure 12-11):

Subsequent hydrolysis of PP_i to two molecules of P_i releases energy that drives this reaction to completion. To enter the mitochondrial matrix, the fatty acyl group must be covalently transferred to a molecule called *carnitine* and moved across the inner mitochondrial membrane by an acylcarnitine transporter protein (see Figure 12-11, blue oval); then, on the matrix side, the fatty acyl group is released from carnitine and reattached to another CoA molecule. The activity of the acylcarnitine transporter is regulated to prevent oxidation of fatty acids when cells have adequate energy (ATP) supplies.

In the first part of stage II, each molecule of a fatty acyl CoA in the mitochondrion is oxidized in a cyclical sequence of four reactions in which all the carbon atoms are converted, two at a time, to acetyl CoA with generation of $FADH_2$ and NADH (Figure 12-15a). For example, mitochondrial oxidation of each molecule of the 18-carbon stearic acid, $CH_3(CH_2)_{16}COOH$, yields nine molecules of acetyl CoA and eight molecules each of NADH and $FADH_2$. In the second part of stage II, as with acetyl CoA generated from pyruvate, these acetyl groups enter the citric acid cycle and are oxidized to CO_2. As will be

described in detail in the next section, the reduced NADH and $FADH_2$ with their high-energy electrons will be used in stage III to generate a proton-motive force, which in turn is used in stage IV to power ATP synthesis.

Peroxisomal Oxidation of Fatty Acids Generates No ATP

Mitochondrial oxidation of fatty acids is the major source of ATP in mammalian liver cells, and biochemists at one time believed this was true in all cell types. However, rats treated with clofibrate, a drug that affects many features of lipid metabolism, were found to exhibit an increased rate of fatty acid oxidation and a large increase in the number of **peroxisomes** in their liver cells. This finding suggested that peroxisomes, as well as mitochondria, can oxidize fatty acids. These small organelles, 0.2–1 μm in diameter, are lined by a single membrane (see Figure 1-12). They are present in all mammalian cells except erythrocytes and are also found in plant cells, yeasts, and probably most other eukaryotic cells.

Mitochondria preferentially oxidize short-chain [fewer than 8 carbons ($<C_8$)], medium-chain (C_8–C_{12}), and long-chain (C_{14}–C_{20}) fatty acids, whereas peroxisomes preferentially oxidize very long chain fatty acids (VLCFAs$>C_{20}$), which cannot be oxidized by mitochondria. Most dietary fatty acids have long chains, which

means that they are oxidized mostly in mitochondria. In contrast to mitochondrial oxidation of fatty acids, which is coupled to generation of ATP, peroxisomal oxidation of fatty acids is not linked to ATP formation, and energy is released as heat.

The reaction pathway by which fatty acids are degraded to acetyl CoA in peroxisomes is similar to that used in mitochondria (Figure 12-15). However, peroxisomes lack an electron-transport chain, and electrons from the $FADH_2$ produced during the oxidation of fatty acids are immediately transferred to O_2 by *oxidases*, regenerating FAD and forming hydrogen peroxide (H_2O_2). In addition to oxidases, peroxisomes contain abundant *catalase*, which quickly decomposes the H_2O_2, a highly cytotoxic metabolite. NADH produced during peroxisomal oxidation of fatty acids is exported and reoxidized in the cytosol; there is no need for a malate-aspartate shuttle here. Peroxisomes also lack the citric acid cycle, so acetyl CoA generated during peroxisomal degradation of fatty acids cannot be oxidized further; instead, it is transported into the cytosol for use in the synthesis of cholesterol (see Chapter 10) and other metabolites.

FIGURE 12-15 Oxidation of fatty acids in mitochondria and in peroxisomes. In both mitochondrial oxidation (a) and peroxisomal oxidation (b), fatty acids are converted to acetyl CoA by a series of four enzyme-catalyzed reactions (shown down the center of the figure). A fatty acyl CoA molecule is converted to acetyl CoA and a fatty acyl CoA shortened by two carbon atoms. Concomitantly, one FAD molecule is reduced to $FADH_2$ and one NAD^+ molecule is reduced to NADH. The cycle is repeated on the shortened acyl CoA until fatty acids with an even number of carbon atoms are completely converted to acetyl CoA. In mitochondria (a), electrons from $FADH_2$ and NADH enter the electron-

transport chain and are ultimately used to generate ATP; the acetyl CoA generated is oxidized in the citric acid cycle, resulting in the release of CO_2 and ultimately the synthesis of additional ATP. Because peroxisomes (b) lack the protein complexes composing the electron-transport chain and the enzymes of the citric acid cycle, oxidation of fatty acids in these organelles yields no ATP.

KEY CONCEPTS OF SECTION 12.5

The Citric Acid Cycle and Fatty Acid Oxidation

- In stage II of glucose oxidation, the three-carbon pyruvate molecule is first oxidized to generate one molecule each of CO_2, NADH, and acetyl CoA. The acetyl group of acetyl CoA is then oxidized to CO_2 by the citric acid cycle (see Figure 12-11).
- Each turn of the citric acid cycle releases two molecules of CO_2 and generates three NADH molecules, one $FADH_2$ molecule, and one GTP (see Figure 12-13).
- Most of the energy released in stages I and II of glucose oxidation is temporarily stored in the reduced coenzymes NADH and $FADH_2$, which carry high-energy electrons that subsequently drive the electron-transport chain (stage III).
- Neither glycolysis nor the citric acid cycle directly uses molecular oxygen (O_2).
- The malate-aspartate shuttle regenerates the supply of cytosolic NAD^+ necessary for continued glycolysis (see Figure 12-14).
- Like glucose oxidation, the oxidation of fatty acids takes place in four stages. In stage I, fatty acids are converted to fatty acyl CoA in the cytosol. In stage II, in the mitochondria the fatty acyl CoA is first converted into multiple acetyl CoA molecules, with generation of NADH and $FADH_2$. Then, as in glucose oxidation, the acetyl CoA enters the citric acid cycle. Stages III and IV are identical for fatty acid and glucose oxidation (see Figure 12-11).
- In most eukaryotic cells, oxidation of short- to long-chain fatty acids occurs in mitochondria with production of ATP, whereas oxidation of very long chain fatty acids occurs primarily in peroxisomes and is not linked to ATP production (see Figure 12-15); the energy released during peroxisomal oxidation of fatty acids is converted to heat.

12.6 The Electron-Transport Chain and Generation of the Proton-Motive Force

Most of the energy released during the oxidation of glucose and fatty acids to CO_2 (stages I and II) is converted into high-energy electrons in the reduced coenzymes NADH and $FADH_2$. We now turn to stage III, in which the energy transiently stored in these reduced coenzymes is converted by an electron-transport chain, also known as the **respiratory chain**, into the proton-motive force. We first describe the logic and components of the electron-transport chain. Next we follow the path of electrons as they flow through the chain and describe the mechanism of **proton pumping** across the inner mitochondrial membrane. We conclude this section with a discussion of the magnitude of the proton-motive force produced by electron transport and proton pumping. In Section 12.7, we will see how the proton-motive force is used to synthesize ATP.

Oxidation of NADH and $FADH_2$ Releases a Substantial Amount of Energy

During electron transport, electrons are released from NADH and $FADH_2$ and eventually transferred to O_2, forming H_2O, according to

the following overall reactions:

$$\begin{gathered}\mathrm{NADH} + \mathrm{H}^{+} + {}^{1}/_{2}\mathrm{O}_{2} \rightarrow \mathrm{NAD}^{+} + \mathrm{H}_{2}\mathrm{O}, \\ \Delta G = -52.6 \text{ kcal/mol} \\ \mathrm{FADH}_{2} + {}^{1}/_{2}\mathrm{O}_{2} \rightarrow \mathrm{FAD} + \mathrm{H}_{2}\mathrm{O}, \\ \Delta G = -43.4 \text{ kcal/mol}\end{gathered}$$

Recall that the conversion of 1 glucose molecule to CO_2 via the glycolytic pathway and citric acid cycle yields 10 NADH and 2 FADH_2 molecules (see Table 12-2). Oxidation of these reduced coenzymes has a total $\Delta G^{\circ\prime}$ of -613 kcal/mol $[10(-52.6) + 2(-43.4)]$. Thus of the total potential free energy present in the chemical bonds of glucose (-686 kcal/mol), about 90 percent is conserved in the reduced coenzymes. Why should there be two different coenzymes, NADH and FADH_2? Although many of the reactions involved in glucose and fatty acid oxidation are sufficiently energetic to reduce NAD^{+}, several are not. To capture the energy released by those reactions, they are coupled to reduction of FAD, which requires less energy.

TABLE 12-2 • Net Result of the Glycolytic Pathway and the Citric Acid Cycle

Reaction	CO_2 Molecules Produced	NAD^{+} Molecules Reduced to NADH	FAD Molecules Reduced to FADH_2	ATP (or GTP)

1 glucose molecule to 2 pyruvate molecules	0	2	0	2
2 pyruvates to 2 acetyl CoA molecules	2	2	0	0
2 acetyl CoA to 4 CO_2 molecules	4	6	2	2
Total	6	10	2	4

The energy carried in the reduced coenzymes can be released by oxidizing them. The biochemical challenge faced by the mitochondrion is to transfer, as efficiently as possible, the energy released by this oxidation into the energy in the terminal phosphoanhydride bond in ATP.

$$\mathrm{P_i^{2-}} + \mathrm{H^+} + \mathrm{ADP^{3-}} \rightarrow \mathrm{ATP^{4-}} + \mathrm{H_2O},$$

$$\Delta G = +7.3 \text{ kcal/mol}$$

A relatively simple one-to-one reaction involving reduction of one coenzyme molecule and synthesis of one ATP molecule would be terribly inefficient because the $\Delta G^{\circ\prime}$ for ATP generation from ADP and $\mathrm{P_i}$ is substantially less than that for the coenzyme oxidation, and much energy would be lost as heat. To efficiently recover that energy, the mitochondrion converts the energy of coenzyme

oxidation into a proton-motive force using a series of electron carriers, all but one of which are integral components of the inner membrane (see stage III in Figure 12-11). The proton-motive force can then be used to generate ATP very efficiently.

Electron Transport in Mitochondria Is Coupled to Proton Pumping

During electron transport from NADH and $FADH_2$ to O_2, protons from the mitochondrial matrix are pumped across the inner membrane. This pumping raises the pH of the mitochondrial matrix relative to the intermembrane space and cytosol and also makes the matrix side of the inner membrane more electrically negative relative to the intermembrane side. In other words, the free energy released during the oxidation of NADH or $FADH_2$ is stored both as a proton concentration gradient and as an electrical voltage gradient across the membrane — collectively known as the *proton-motive force* (see Figure 12-2). As we will see in Section 12.7, the movement of protons back across the inner membrane, driven by this force, is coupled to the synthesis of ATP from ADP and P_i by ATP synthase (stage IV).

The synthesis of ATP from ADP and P_i, driven by the energy released by transfer of electrons from NADH or $FADH_2$ to O_2, is the major source of ATP in aerobic non-photosynthetic cells. Much

evidence shows that in mitochondria and bacteria, this process of oxidative phosphorylation depends on the generation of a proton-motive force across the inner membrane (in mitochondria) or bacterial plasma membrane, with electron transport, proton pumping, and ATP formation occurring simultaneously. In the laboratory, for instance, addition of O_2 and an oxidizable substrate such as pyruvate or succinate to isolated intact mitochondria results in net synthesis of ATP if the inner mitochondrial membrane is intact. In the presence of minute amounts of detergents that make the membrane leaky, electron transport and the oxidation of these metabolites by O_2 still occurs. However, no ATP is made under these conditions because the proton leak prevents the maintenance of the proton-motive force.

The coupling between electron transport from NADH (or $FADH_2$) to O_2 and proton transport across the inner mitochondrial membrane can also be demonstrated experimentally, with isolated, intact mitochondria (Figure 12-16). As soon as O_2 is added to a suspension of mitochondria in an otherwise O_2-free solution that contains NADH, the medium outside the mitochondria transiently becomes more acidic (increased proton concentration) because the mitochondrial outer membrane is freely permeable to protons. (Remember that the malate-aspartate shuttle and other shuttles can convert the NADH in the solution into NADH in the mitochondrial matrix.) Once the O_2 is depleted by its reduction, the excess protons in the medium slowly leak back into the matrix. By measuring the

pH change in such experiments, one can calculate that about 10 protons are transported out of the matrix for every electron pair transferred from NADH to O_2.

EXPERIMENTAL FIGURE 12-16 Electron transfer from NADH to O_2 is coupled to proton transport across the mitochondrial membrane. If NADH is added to a suspension of mitochondria depleted of O_2 (experimental apparatus shown in the inset), no NADH is oxidized. When a small amount of O_2 is added to the system (arrow), there is a sharp rise in the concentration of protons as a function of time in the surrounding medium outside the mitochondria (decrease in pH). Thus the oxidation of NADH by O_2 is coupled to the movement of protons out of the matrix into the intermembrane space and then to the surrounding media. Once the O_2 is depleted, the excess protons slowly move back into the mitochondria (powering the synthesis of ATP), and the pH of the extracellular medium returns to its initial value.

To obtain numbers for $FADH_2$, this experiment can be repeated using succinate instead of NADH as the substrate. (Recall that oxidation of succinate to fumarate in the citric acid cycle generates $FADH_2$; see Figure 12-13.) The amount of succinate added can be adjusted so that the amount of $FADH_2$ generated is equivalent to the amount of NADH in the first experiment. As in the first experiment, addition of O_2 causes the medium outside the mitochondria to become acidic, but less so than with NADH. This difference is not surprising, because electrons in $FADH_2$ have less potential energy (43.4 kcal/mol) than electrons in NADH (52.6 kcal/mol), and thus $FADH_2$ drives the translocation of fewer protons from the matrix and a smaller change in pH.

Electrons Release Energy as They Flow Downhill Through a Series of Electron Carriers

Let's examine more closely the energetically favored movement of electrons from NADH and $FADH_2$ to the final electron acceptor, O_2. For simplicity, we will focus our discussion on NADH. In respiring mitochondria, each NADH molecule releases two electrons to the electron-transport chain; these electrons ultimately reduce one oxygen atom (half of an O_2 molecule), forming one molecule of water:

$$\mathrm{NADH} \rightarrow \mathrm{NAD}^+ + \mathrm{H}^+ + 2\mathrm{e}^-$$
$$2\,\mathrm{e}^- + 2\,\mathrm{H}^+ + {}^1/_2\mathrm{O}_2 \rightarrow \mathrm{H}_2\mathrm{O}$$

As electrons move from NADH to O_2, their electric potential declines by 1.14 V, which corresponds to $26.29\,\mathrm{kcal/mol}$ of electrons transferred, or about $53\,\mathrm{kcal/mol}$ for a pair of electrons. As noted earlier, much of this energy is conserved in the proton-motive force generated across the inner mitochondrial membrane.

Four large multiprotein complexes (complexes I–IV) compose the electron-transport chain in the inner mitochondrial membrane that is responsible for the generation of the proton-motive force (see Figure 12-11, stage III). Each complex contains several **prosthetic groups** that participate in the process of moving electrons from donor molecules to acceptor molecules in coupled oxidation-reduction reactions (see Chapter 2). These small nonpeptide organic molecules or metal ions are tightly and specifically associated with the multiprotein complexes (Table 12-3).

Heme and the Cytochromes

Several types of *heme*, an iron-containing prosthetic group similar to that found in hemoglobin and myoglobin (Figure 12-17a), are tightly bound (covalently or noncovalently) to a set of mitochondrial proteins called **cytochromes**. Each cytochrome is designated by a

letter, such as *a, b, c,* or c_1. Electron flow through the cytochromes occurs by oxidation and reduction of the Fe atom in the center of the heme molecule:

$$Fe^{3+} + e^- \rightleftharpoons Fe^{2+}$$

FIGURE 12-17 Heme and iron-sulfur prosthetic groups in the electron-transport chain. (a) Heme portion of cytochromes b_L and b_H, which are components of $CoQH_2$–cytochrome *c* reductase (complex III). The same porphyrin ring (yellow) is present in all hemes. The chemical substituents attached to the porphyrin ring differ in the other cytochromes in the electron-transport chain. All hemes accept and release one electron at a time. (b) Dimeric iron-sulfur cluster (Fe-S). Each Fe atom is bonded to four S atoms: two are inorganic sulfur, and two are in cysteine side chains of the associated protein. All Fe-S clusters accept and release one electron at a time.

Because the heme ring in cytochromes consists of alternating double- and single-bonded atoms, a large number of resonance hybrid forms exist. These forms allow the extra electron delivered to

the cytochrome to be spread throughout the heme carbon and nitrogen atoms as well as the Fe ion.

The various cytochromes each have slightly different heme groups and surrounding atoms, which generate different environments for the Fe ion. Therefore, each cytochrome has a different reduction potential, or tendency to accept an electron — an important property that dictates the unidirectional, energetically downhill electron flow along the chain. Just as water spontaneously flows downhill from a higher to a lower potential energy state — but not uphill — electrons flow in only one direction from one heme (or other prosthetic group) to another due to their differing reduction potentials. (For more on the concept of reduction potential, *E*, see Chapter 2.) As we will see shortly, all the cytochromes except cytochrome *c* are components of integral membrane multiprotein complexes in the inner mitochondrial membrane.

Iron-Sulfur Clusters

Iron-sulfur clusters are nonheme, iron-containing prosthetic groups consisting of Fe atoms bonded both to inorganic sulfur (S) atoms and to S atoms on cysteine residues in a protein (Figure 12-17b). Some Fe atoms in the cluster bear a $+2$ charge; others have a $+3$ charge. However, the net charge of each Fe atom is actually between $+2$ and $+3$, because electrons in their outermost orbitals, together with the extra electron delivered via the transport chain, are

dispersed among the Fe atoms and move rapidly from one atom to another. Iron-sulfur clusters accept and release electrons one at a time.

Coenzyme Q

Also called **ubiquinone, Coenzyme Q (CoQ)** is the only small-molecule electron carrier in the electron-transport chain that is not an essentially irreversibly protein-bound prosthetic group (Figure 12-18). It is a carrier of both protons and electrons. The oxidized quinone form of CoQ can accept a single electron to form a semiquinone, a negatively charged free radical denoted by $CoQ^{\bullet -}$, where the superscript dot ($^{\bullet}$) indicates an unpaired and reactive electron. Addition of a second electron and two protons (thus a total of two hydrogen atoms) to $CoQ^{\bullet -}$ forms dihydroubiquinone ($CoQH_2$), the fully reduced form. Both CoQ and $CoQH_2$ are hydrophobic, and thus are soluble in phospholipids and diffuse freely in the hydrophobic center of the inner mitochondrial membrane. These properties underlie ubiquinone's role in the electron-transport chain: carrying electrons and protons between the membrane-embedded protein complexes of the chain.

FIGURE 12-18 Oxidized and reduced forms of coenzyme Q (CoQ), which can carry two protons and two electrons. Because of its long hydrocarbon "tail" of isoprene units, CoQ, also called *ubiquinone*, is soluble in the hydrophobic core of phospholipid bilayers and is very mobile. Reduction of CoQ to the fully reduced form, QH_2 (dihydroquinone), occurs in two steps with a half-reduced free-radical intermediate, called *semiquinone*.

Four Large Multiprotein Complexes (I–IV) Couple Electron Transport to

Proton Pumping Across the Inner Mitochondrial Membrane

We now consider in detail the multiprotein complexes that use these prosthetic groups and the paths taken by electrons and protons as they pass through these complexes.

As electrons flow downhill from one electron carrier to the next in the electron-transport chain, the energy released is used to power the pumping of protons out of the matrix against their electrochemical gradient across the inner mitochondrial membrane. Four large multiprotein complexes (Figure 12-19) directly or indirectly couple the movement of electrons to proton pumping: *NADH-CoQ reductase* (complex I, >40 protein subunits), *succinate-CoQ reductase* (complex II, 4 subunits), $CoQH_2$*–cytochrome* c *reductase* (complex III, 11 subunits), and *cytochrome* c *oxidase* (complex IV, 13 subunits). The electrons follow one of two routes through these complexes: I $\rightarrow$ III $\rightarrow$ IV or II $\rightarrow$ III $\rightarrow$ IV. In addition, complexes I, III, and IV all pump protons directly across the inner membrane, whereas complex II does not (see Figure 12-19). Electrons from NADH flow from complex I via $\mathrm{CoQ/CoQH_2}$ to complex III and then, via the soluble protein cytochrome *c* (cyt *c*), to complex IV which reduces molecular oxygen (complex II is bypassed) (see Figure 12-19a). Electrons from $\mathrm{FADH_2}$ flow from complex II via $\mathrm{CoQ/CoQH_2}$ to complex III (see Figure 12-19b) and

then via cytochrome *c* to complex IV to reduce molecular oxygen (complex I is bypassed).

As shown in Figure 12-19, CoQ accepts electrons released from NADH-CoQ reductase (complex I) or succinate-CoQ reductase (complex II) and donates them to $CoQH_2$–cytochrome *c* reductase (complex III). Protons are simultaneously transported from the matrix side of the membrane (also called the *cytosolic side*) to the intermembrane space (also called the *exoplasmic side*). Whenever CoQ accepts electrons, it does so at a binding site on the matrix side of a protein complex, always picking up protons from the medium there. Whenever $CoQH_2$ releases its electrons, it does so at a site on the intermembrane space side of a protein complex, releasing protons into the fluid of the intermembrane space. Thus the transport of each pair of electrons by CoQ is obligately coupled to the movement of two protons from the matrix to the intermembrane space.

FIGURE 12-19 The mitochondrial electron-transport chain. Electrons (blue arrows) flow through four major multiprotein complexes (I–IV). Electron movement between complexes is mediated either by the lipid-soluble molecule coenzyme Q (CoQ, oxidized form; $\mathrm{CoQH_2}$, reduced form) or the water-soluble protein cytochrome *c* (cyt *c*) in the intermembrane space. Three of the multiprotein complexes use the energy released from the electrons to pump protons (red arrows) from the matrix (cytosolic compartment in bacteria) to the intermembrane space (exoplasmic space of bacteria). (a) Pathway from NADH. Two electrons from NADH $(2/\mathrm{NADH\ oxidized})$ flow through complex I, initially via a flavin mononucleotide (FMN) and then one at a time via seven iron-sulfur clusters (Fe-S), to CoQ, to which two protons bind, forming $\mathrm{CoQH_2}$. Conformational changes in complex I that accompany the electron flow drive proton pumping from the matrix to the intramembrane space. Electrons then flow via the released (and subsequently recycled) $\mathrm{CoQH_2}$ to complex III, and then via cyt *c* to complex IV. Each of four cyt *c* molecules carrying four electrons originating from two NADHs transfers individual electrons to complex IV for the four-electron reduction of one $\mathrm{O_2}$ molecule to two $\mathrm{H_2O}$ molecules and transport of four protons. Thus for every two NADHs oxidized and one $\mathrm{O_2}$ molecule reduced, a total of 20 protons are translocated out of the matrix into the intermembrane space. (b) Pathway from succinate. Two electrons flow from each succinate to complex II via $\mathrm{FAD/FADH_2}$ and iron-sulfur clusters (Fe-S), from complex II to complex III via $\mathrm{CoQ/CoQH_2}$, and then to complex IV via cyt *c*. Electrons released during oxidation of succinate to fumarate in complex II are used to reduce CoQ to $\mathrm{CoQH_2}$ without translocating additional protons. The remainder of electron transport from $\mathrm{CoQH_2}$ proceeds by the same pathway as for the NADH pathway in (a). Thus for every two succinates oxidized and one $\mathrm{O_2}$ molecule reduced,12 protons (8 via the Q-cycle of complex III that is described below, 4 via complex IV) are translocated.

NADH-CoQ Reductase (Complex I)

Electrons are transferred from NADH to CoQ by NADH-CoQ reductase (see Figure 12-19a). Electron microscopy and x-ray crystallography of complex I from bacteria (mass $\sim$500 kDa, with 14 subunits) and from eukaryotes ($\sim$1.7 MDa, with 14 highly conserved core subunits, which are also present in bacteria, plus about 26–32

accessory subunits) has established that it is L-shaped (Figure 12-20a). The membrane-embedded arm of the L is slightly curved, about 180 Å long, and comprises proteins with more than 60 transmembrane α helices. This arm has four subdomains, three of which contain proteins that are members of a family of cation antiporters. The hydrophilic peripheral arm extends over 95 Å away from the membrane into the matrix (cytosolic) space.

FIGURE 12-20 Electron and proton transport through complexes I and II. (a) Model of complex I based on its three-dimensional structure. The outline of the shape of the core complex I from the yeast *Yarrowia lipolytica*, as determined by x-ray crystallography, is shown in light blue, and the borders separating several distinct structural subunits are indicated by thin dashed black lines. From NADH, electrons flow first to a flavin mononucleotide (FMN) and then, via iron-sulfur clusters (Fe-S, red and yellow balls), to CoQ, to which two protons from the matrix bind (red arrow) to form $\mathrm{CoQH_2}$. Conformational changes due to the electron flow, which may include a horizontal movement of the t-helix, drive proton pumping through the transmembrane subunits from the matrix to the intramembrane space (red arrows). (b) Model of complex II based on its three-dimensional structure. Electrons flow through complex II from succinate to CoQ via $\mathrm{FAD/FADH_2}$ and

iron-sulfur clusters (Fe-S), and from complex II to complex III via $\mathrm{CoQ/CoQH_2}$. Electrons released during oxidation of succinate to fumarate in complex II are used to reduce CoQ to $\mathrm{CoQH_2}$ without translocating additional protons.

[Part (a) Data from V. Zickermann et al., 2015, *Science* **347**:44–49, PDB ID 3m9s. Part (b) data from F. Sun et al., 2005, *Cell* **121**:1043–1057, PDB ID 1zoy.]

$\mathrm{NAD^+}$ is exclusively a two-electron carrier: it accepts (or for NADH releases) a pair of electrons simultaneously. In NADH-CoQ reductase (complex I), the NADH-binding site is at the tip of the peripheral arm (see Figure 12-20a); electrons released from NADH first flow to FMN (flavin mononucleotide), a prosthetic group, or cofactor, related to FAD, then are shuttled about 95 Å down the peripheral arm through a series of iron-sulfur clusters and finally to CoQ, which is bound at a site at least partially in the plane of the membrane. FMN, like FAD, can accept two electrons, but does so one electron at a time.

Each transported electron undergoes a drop in potential of about 360 mV, equivalent to a $\Delta G^{\circ\prime}$ of $-16.6\,\mathrm{kcal/mol}$ for the two electrons transported. Much of this released energy is used to transport four protons across the inner membrane per molecule of NADH oxidized by complex I. These four protons are distinct from the two protons that are transferred to the CoQ as illustrated in Figures 12-18, 12-19a, and 12-20a. The precise mechanism by which the energy released by electron transport in the peripheral arm is used to change the conformation of subunits in the membrane arm and thus mediate the movement of four protons across the membrane is uncertain.

Three protons are likely to pass through the three cation antiporter domains via a zigzag series of polar side chains that can be protonated and that span the membrane. A similar series of side chains is the likely conduit for the fourth proton. A transverse α helix (t-helix) in the membrane arm runs parallel to the plane of the membrane, potentially mechanically linking the antiporter-like domains to the peripheral arm (see Figure 12-20a) and possibly contributing directly to the conformational changes required to convert the energy released by the electron transport in the peripheral arm into proton transport by the transmembrane domains.

The overall reaction catalyzed by this complex is

$$\underset{\text{(Reduced)}}{\text{NADH}} + \underset{\text{(Oxidized)}}{\text{CoQ}} + 6\,\text{H}^+{}_{\text{matrix}} \rightarrow \underset{\text{(Oxidized)}}{\text{NAD}^+} + \text{H}^+{}_{\text{in}} + \underset{\text{(Reduced)}}{\text{CoQH}_2} + 4\,\text{H}^+{}_{\text{interme}}$$

Succinate-CoQ Reductase (Complex II)

Succinate dehydrogenase, the enzyme that oxidizes a molecule of succinate to fumarate in the citric acid cycle (and in the process generates the reduced coenzyme FADH_2), is one of the four subunits of complex II (Figure 12-20b). Thus the citric acid cycle is physically as well as functionally linked to the electron-transport chain. The two electrons released in the conversion of succinate to fumarate are transferred first to FAD in succinate dehydrogenase,

then to iron-sulfur clusters — regenerating FAD — and finally to CoQ, which binds to a cleft on the matrix side of the transmembrane portions of complex II (see Figures 12-19b and 12-20b). The pathway is somewhat reminiscent of that in complex I (see Figure 12-20a).

The overall reaction catalyzed by this complex is

$$\underset{\text{(Reduced)}}{\text{NADH}} + \underset{\text{(Oxidized)}}{\text{CoQ}} + 6\,\text{H}^+{}_{\text{matrix}} \rightarrow \underset{\text{(Oxidized)}}{\text{NAD}^+} + \text{H}^+{}_{\text{in}} + \underset{\text{(Reduced)}}{\text{CoQH}_2} + 4\,\text{H}^+{}_{\text{intermem}}$$

Although the $\Delta G^{\circ\prime}$ for this reaction is negative, the released energy is insufficient for proton pumping in addition to reduction of CoQ to form CoQH_2. Thus no protons are translocated directly across the membrane by succinate-CoQ reductase (complex II), and no proton-motive force is generated in this part of the electron-transport chain. We will see shortly how the protons and electrons in the CoQH_2 molecules generated by complexes I and II contribute to the generation of the proton-motive force.

Complex II generates CoQH_2 from succinate via FAD/FADH_2-mediated redox reactions. Another set of proteins in the matrix and inner mitochondrial membrane performs a comparable set of FAD/FADH_2-mediated redox reactions. As with succinate dehydrogenase, these proteins, described in detail in the following paragraph and Figure 12-15, use FADH_2 to produce CoQH_2, which contributes electrons to the electron-transport chain.

Fatty acyl–CoA dehydrogenase (see Figure 12-15), which is a water-soluble enzyme, catalyzes the first step of the oxidation of fatty acyl CoA in the mitochondrial matrix. There are several fatty acyl–CoA dehydrogenase enzymes with specificities for fatty acyl chains of different lengths. These enzymes mediate the initial step in a four-step process that removes two carbons from the fatty acyl group by oxidizing the carbon in the β position of the fatty acyl chain (thus the entire process is often referred to as *β-oxidation*). These reactions generate acetyl CoA, which in turn enters the citric acid cycle. They also generate an $FADH_2$ intermediate and NADH. The $FADH_2$ generated remains bound to the enzyme during the redox reaction, as is the case for complex II. A water-soluble protein called *electron transfer flavoprotein (ETF)* transfers the high-energy electrons from the $FADH_2$ in the fatty acyl–CoA dehydrogenase to *electron transfer flavoprotein:ubiquinone oxidoreductase (ETF:QO)*, a membrane protein that reduces CoQ to $CoQH_2$ in the inner membrane. This $CoQH_2$ intermixes in the membrane with the other $CoQH_2$ molecules generated by complexes I and II, all contributing to proton transport out of the matrix by complex III.

$CoQH_2$–Cytochrome *c* Reductase (Complex III)

A $CoQH_2$ generated by complex I, complex II, or ETF:QO donates two electrons to $CoQH_2$–cytochrome *c* reductase (complex III), regenerating oxidized CoQ. Concomitantly, it releases into the intermembrane space two protons previously picked up by CoQ on

the matrix face, generating part of the proton-motive force (see Figure 12-19). Within complex III, the released electrons are first transferred to an iron-sulfur cluster within the complex and then to cytochrome c_1 or to two *b*-type cytochromes (b_L and b_H, see the discussion of the Q cycle below). Finally, the two electrons are transferred sequentially to two molecules of the oxidized form of cytochrome *c*, a water-soluble peripheral protein that diffuses in the intermembrane space. For each pair of electrons transferred, the overall reaction catalyzed by complex III is

$$\underset{\text{(Reduced)}}{\mathrm{CoQH_2}} + \underset{\text{(Oxidized)}}{2\,\mathrm{Cyt}\,c^{3+}} + 2\,\mathrm{H^+}_{\mathrm{in}} \rightarrow \underset{\text{(Oxidized)}}{\mathrm{CoQ}} + 4\,\mathrm{H^+}_{\mathrm{out}} + \underset{\text{(Reduced)}}{2\,\mathrm{Cyt}\,c^{2+}}$$

The $\Delta G^{\circ\prime}$ for this reaction is sufficiently negative that two protons in addition to those from $\mathrm{CoQH_2}$ are translocated from the mitochondrial matrix across the inner membrane for each pair of electrons transferred; this transfer involves the proton-motive Q cycle, discussed immediately below. The heme protein cytochrome *c* and the small lipid-soluble molecule CoQ play similar roles in the electron-transport chain in that they both serve as mobile electron shuttles, transferring electrons (and thus energy) between the complexes of the electron-transport chain.

The Q Cycle

Experiments have shown that four protons are translocated across the inner mitochondrial membrane per electron pair transported from $CoQH_2$ through complex III. These four protons are those carried on two $CoQH_2$ molecules, which are converted to two CoQ molecules during the cycle. However, during this process another CoQ molecule receives two other protons from the matrix and is converted to one $CoQH_2$ molecule. Thus the net overall reaction involves the conversion of only one $CoQH_2$ molecule to CoQ as two electrons are transferred, one at a time, to two molecules of the acceptor cytochrome *c*. An evolutionarily conserved mechanism, called the **Q cycle**, is responsible for the two-for-one transport of protons and electrons by complex III (Figure 12-21).

$CoQH_2$–cytochrome *c* reductase (complex III)

At Q_o site: $2\ CoQH_2 + 2\ Cyt\ c^{3+} \longrightarrow$
$(4\ H^+, 4\ e^-)$
$2\ CoQ + 2\ Cyt\ c^{2+} + 2\ e^- + 4\ H^+_{\text{intermembrane space/exoplasmic side}}$
$(2\ e^-)$

At Q_i site: $CoQ + 2\ e^- + 2\ H^+_{\text{matrix/cytosolic side}} \longrightarrow CoQH_2$
$(2\ H^+, 2\ e^-)$

Net Q cycle (sum of reactions at Q_o and Q_i):

$CoQH_2 + 2\ Cyt\ c^{3+} + 2\ H^+_{\text{matrix/cytosolic side}} \longrightarrow$
$(2\ H^+, 2\ e^-)$
$CoQ + 2\ Cyt\ c^{2+} + 4\ H^+_{\text{intermembrane space/exoplasmic side}}$
$(2\ e^-)$

Per $2\ e^-$ transferred through complex III to cytochrome *c*, $4\ H^+$ released to the intermembrane space

FIGURE 12-21 The Q cycle. The Q cycle of complex III uses the net oxidation of one $CoQH_2$ molecule to transfer four protons into the intermembrane space and two electrons to two cytochrome *c* molecules. The cycle begins (step **1**) when a molecule from the combined pool of reduced $CoQH_2$ in the inner mitochondrial membrane binds to the Q_o site on the *intermembrane space (exoplasmic) side* of the transmembrane portion of complex III. There in step **2a** $CoQH_2$ releases two protons into the intermembrane space and in step **3** two electrons and the resulting CoQ dissociate. In step **2b**, one of the

electrons is transported, via an iron-sulfur protein and cytochrome c_1, directly to cytochrome *c*. (Recall that each cytochrome *c* shuttles one electron from complex III to complex IV.) In step **4**, the other electron moves through cytochromes b_L and b_H and partially reduces an oxidized CoQ molecule already bound to the second, Q_i, site on the *matrix (cytosolic) side* of the complex, forming a CoQ semiquinone anion, $Q^{\bullet -}$. The process is then repeated with step **5**: the binding of a second $CoQH_2$ at the Q_o site, step **6a**: proton release, step **6b**: reduction of another cytochrome *c*, and step **7**: addition of the other electron to the $Q^{\bullet -}$ bound at the Q_i site. In steps **8** and **9** the addition of two protons from the matrix yields a fully reduced $CoQH_2$ molecule at the Q_i site, which then dissociates, that leads to step **10**, the freeing the Q_i to bind a new molecule of CoQ and the Q cycle begins over again. See B. Trumpower, 1990, *J. Biol. Chem.* **265**:11409; and E. Darrouzet et al., 2001, *Trends Biochem. Sci*. **26**:445.

The substrate for complex III, $CoQH_2$, is generated by several enzymes, including NADH-CoQ reductase (complex I), succinate-CoQ reductase (complex II), ETF:QO (during β-oxidation), and as we shall see, by complex III itself.

As shown in Figure 12-21, in one turn of the Q cycle, two molecules of $CoQH_2$ are oxidized to CoQ at the Q_o site near the intermembrane space in complex III and release a total of four protons into the intermembrane space. In addition, at a different CoQ binding site near the matrix side of complex III called the *Q_i site*, one molecule of $CoQH_2$ is regenerated from CoQ and two additional protons from the matrix. The translocated protons are all derived from $CoQH_2$, which obtained its protons from the matrix, as described above. Although seemingly cumbersome, the Q cycle optimizes the number

of protons pumped per pair of electrons moving through complex III. The Q cycle is found in all plants and animals as well as in bacteria. Its formation at a very early stage of cellular evolution was probably essential for the success of all life forms as a way of converting the potential energy in reduced coenzyme Q ($CoQH_2$) into the maximum proton-motive force across a membrane. In turn, this process maximizes the number of ATP molecules synthesized from each electron that moves down the electron-transport chain from NADH or $FADH_2$ to O_2.

How are the two electrons released from $CoQH_2$ at the Q_o site directed to different acceptors, either to Fe-S, cytochrome c_1, and then cytochrome *c* (upward pathway in Figure 12-21), or alternatively to cytochrome b_L, cytochrome b_H, and then CoQ at the Q_i site (downward pathway in Figure 12-21)? The mechanism involves a flexible hinge in the Fe-S–containing protein subunit of complex III. Initially, the Fe-S cluster is close enough to the Q_o site to pick up an electron from $CoQH_2$ bound there. Once this happens, the subunit containing this Fe-S cluster swings the cluster away from the Q_o site to a position near enough to the heme on cytochrome c_1 for electron transfer to occur. With the Fe-S–containing subunit in this alternate conformation, the second electron released from the $CoQH_2$ bound to the Q_o site cannot move to the Fe-S cluster — it is too far away, so it takes an alternative path open to it via a somewhat less thermodynamically favored route to cytochrome b_L and through cytochrome b_H to the CoQ at the Q_i site.

Cytochrome *c* Oxidase (Complex IV)

Cytochrome *c*, after being reduced by one electron from complex III, is reoxidized when it transports its electron to cytochrome *c* oxidase (complex IV) (see Figure 12-19a). Mitochondrial cytochrome *c* oxidases contain 13 different subunits, but the catalytic core of the enzyme consists of only three. The functions of the remaining subunits are not well understood. Bacterial cytochrome *c* oxidases contain only the three catalytic subunits. In both mitochondria and bacteria, four molecules of reduced cytochrome *c* bind, one at a time, to the oxidase. Figure 12-19a shows how an electron is transferred from the heme of each cytochrome *c*, first to the pair of copper ions labeled $Cu_a{}^{2+}$, then to the heme in cytochrome *a*. Next the electron moves to the oxygen reduction center, composed of $Cu_b{}^{2+}$ and the heme in cytochrome a_3, which together bind in a sandwich fashion and sequester the O_2 molecule that will be reduced to two H_2Os. Several lines of evidence suggest that O_2 reaches the reduction center via one or more hydrophobic channels through the protein, into which O_2 flows from the hydrophobic core of the membrane, where it is more soluble than in aqueous solution (see Figure 12-19a).

The four electrons are finally passed by complex IV to O_2, the ultimate electron acceptor, yielding two H_2O, which together with CO_2 is one of the end products of the overall oxidation pathway. Proposed intermediates in oxygen reduction include the peroxide

anion ($O_2{}^{2-}$) and the hydroxyl radical ($OH^{\bullet}$), as well as unusual complexes of iron and oxygen atoms. These intermediates would be harmful to the cell if they escaped from complex IV, but they do so only rarely because they are sequestered by the $Cu_b{}^{2+}$ and the heme in cytochrome a_3. To generate H_2O from the reduced O_2, protons are channeled to the oxygen reduction center. In addition, other protons are transported across the membrane from the matrix to the intermembrane space. During the transport of four electrons through the cytochrome *c* oxidase complex, four protons from the matrix are translocated across the membrane. Thus complex IV transports only one proton per electron transferred, whereas complex III, using the Q cycle, transports two protons per electron transferred. However, the mechanism by which complex IV translocates these protons and energetically couples the translocation to O_2 reduction is not fully understood.

For each four electrons transferred, the overall reaction catalyzed by cytochrome *c* oxidase is

$$\underset{\text{(Reduced)}}{4\,\text{cyt}\,c^{2+}} + 8\,H^{+}{}_{\text{matrix}} + O_2 \rightarrow \underset{\text{(Oxidized)}}{4\,\text{cyt}\,c^{3+}} + 2\,H_2O + 4\,H^{+}{}_{\text{intermembrane sp}}$$

The poison cyanide, which has been used as a chemical warfare agent, by spies to commit suicide when captured, in gas chambers to execute prisoners, and by the Nazis (Zyklon B gas) for the mass murder of Jews and others, is toxic because it binds to the heme a_3

in mitochondrial cytochrome *c* oxidase (complex IV), inhibiting electron transport and thus oxidative phosphorylation and production of ATP. Cyanide is one of many toxic small molecules that interfere with energy production in mitochondria. ■

The Reduction Potentials of Electron Carriers in the Electron-Transport Chain Favor Electron Flow from NADH to O_2

As we saw in Chapter 2, the **reduction potential (*E*)** for a partial reduction reaction

$$\text{Oxidized molecule} + e^- \rightleftharpoons \text{reduced molecule}$$

is a measure of the equilibrium constant of that partial reaction. With the exception of the *b* cytochromes in complex III ($CoQH_2$–cytochrome *c* reductase), the standard reduction potential $E^{\circ\prime}$ of the electron carriers in the electron-transport chain increases steadily from NADH to O_2. For instance, for the partial reaction

$$NAD^+ + H^+ + 2\,e^- \rightleftharpoons NADH$$

the value of the standard reduction potential is $-320\,\mathrm{mV}$, which is equivalent to a $\Delta G^{\circ\prime}$ of $+14.8\,\mathrm{kcal/mol}$ for transfer of two electrons. Thus this partial reaction tends to proceed toward the left: that is, toward the oxidation of NADH to $\mathrm{NAD^+}$.

In contrast, the standard reduction potential for the partial reaction

$$\text{Cytochrome } c_{\mathrm{ox}}\,(\mathrm{Fe^{3+}}) + \mathrm{e^-} \rightleftharpoons \text{ cytochrome } c_{\mathrm{red}}\,(\mathrm{Fe^{2+}})$$

is $+220\,\mathrm{mV}$ ($\Delta G^{\circ\prime} = -5.1\,\mathrm{kcal/mol}$) for transfer of one electron. Thus this partial reaction tends to proceed toward the right: that is, toward the reduction of cytochrome *c* ($\mathrm{Fe^{3+}}$) to cytochrome *c* ($\mathrm{Fe^{2+}}$).

The final reaction in the electron-transport chain, the reduction of $\mathrm{O_2}$ to $\mathrm{H_2O}$

$$2\,\mathrm{H^+} + {}^1\!/_2\mathrm{O_2} + 2\,\mathrm{e^-} \rightarrow \mathrm{H_2O}$$

has a standard reduction potential of $+816\,\mathrm{mV}$ ($\Delta G^{\circ\prime} = -37.8\,\mathrm{kcal/mol}$ for transfer of two electrons), the most positive in the whole series; thus this reaction also tends to proceed toward the right.

As illustrated in Figure 12-22, the steady increase from the top left to the bottom right in $E^{\circ\prime}$ values, and the corresponding decrease in

$\Delta G^{\circ\prime}$ values of the carriers in the electron-transport chain favors the flow of electrons from NADH and $FADH_2$ (generated from succinate) to O_2. The energy released as electrons flow energetically downhill through the electron-transport chain complexes drives the pumping of protons against their concentration gradient across the inner mitochondrial membrane.

FIGURE 12-22 Changes in reduction potential and free energy during the stepwise flow of electrons through the electron-transport chain. Blue arrows indicate electron flow; red arrows, translocation of protons across the inner mitochondrial membrane. Electrons pass

through the multiprotein complexes from those with a lower reduction potential to those with a higher (more positive) reduction potential (*left* scale), with a corresponding reduction in free energy (*right* scale). The energy released as electrons flow through three of the complexes is sufficient to power the pumping of H^+ ions across the membrane from the matrix to the intermembrane space (IMS), establishing a proton-motive force.

The Multiprotein Complexes of the Electron-Transport Chain Assemble into Supercomplexes

Over 50 years ago, Britton Chance proposed that the electron-transport complexes might assemble into large **supercomplexes**. Doing so would bring the complexes into close and highly organized proximity, which might improve the speed and efficiency of the overall electron-transport process. Indeed, genetic, biochemical, and biophysical studies have provided very strong evidence for the existence of electron-transport chain supercomplexes. For example, polyacrylamide gel electrophoretic methods called *blue native (BN)-PAGE* and *colorless native (CN)-PAGE*, which permit separation of very large macromolecular protein complexes, have allowed detection of multiple inner mitochondrial membrane supercomplexes with various stoichiometries (Figure 12-23a). When one such supercomplex containing one copy each of complexes I and IV and two copies of complex III ($I/III_2/IV$) was isolated with ubiquinone (CoQ) and cytochrome *c* from BN-PAGE gels, it was shown to transfer electrons from NADH to O_2; in other words, this

supercomplex can respire — it is a respirasome. The structures of two of such supercomplexes from human mitochondria determined by cryo-EM are shown in Figure 12-23b ($I/III_2/IV + 2$ cytochrome *c*'s) and 12-23c ($I/III_2/IV + 2$ cytochrome *c*'s). The precise function of supercomplex formation in the context of the very high protein concentration in the inner mitochondrial membrane remains to be established with certainty, but is thought to involve improving the speed and efficiency of electron transport, stabilizing individual multiprotein complexes, or preventing inappropriate protein aggregates.

EXPERIMENTAL FIGURE 12-23 Electrophoresis and cryoelectron microscopic imaging have identified and permitted high-resolution structure determination of electron-transport chain supercomplexes containing complexes I, III, and IV. (a) Membrane proteins in isolated bovine heart mitochondria were solubilized with a detergent, and the complexes and supercomplexes were separated by gel electrophoresis (see Chapter 3) using the blue native (BN)-PAGE method. Each blue-stained band within the gel represents the indicated protein complex or supercomplex. The intensity of the blue stain is approximately proportional to the amount of complex or supercomplex present. The supercomplex $\mathrm{I/III_2/IV}$ has an apparent molecular weight of ~$1.7\,\mathrm{MDa}$. (b and c) Supercomplexes $\mathrm{I/III_2/IV} + 2$ cytochrome *c*'s and $\mathrm{I_2/III_2/IV_2} + 2$ cytochrome *c*'s were isolated by sucrose

density gradient centrifugation from detergent extracted mitochondria from human HEK293 cultured cells. Cryo-EM imaging methods were used to determine the structures at overall resolutions of $3.9\,\text{Å}$ ($\mathrm{I}/\mathrm{III}_2/\mathrm{IV} + 2$ cytochrome *c*'s) and $17.4\,\text{Å}$ ($\mathrm{I}_2/\mathrm{III}_2/\mathrm{IV}_2 + 2$ cytochrome *c*'s). (b) The left image shows the three-dimensional surface structure of supercomplex $\mathrm{I}/\mathrm{III}_2/\mathrm{IV} + 2$ cytochrome *c*'s viewed from an orientation parallel to the presumptive plane of the membrane. The right image is a molecular model showing the individual complexes: complex I (the peripheral "matrix" arm is dark blue and the membrane-embedded arm is light blue), dimer of complex III (gold), complex IV (green) and cytochrome c (Cyt c, orange/brown). Additional atoms in associated small molecules (such as the iron sulfur clusters in complex I and lipids) are colored as follows: carbon, white; iron, burnt orange; sulfur, yellow; oxygen, red; phosphorous, orange; and nitrogen, blue. The same color scheme is used in panel (c). The data permitted the structure of most of the supercomplex to be determined. For example, the locations of all 45 protein subunits in complex I and most of their 8499 amino acid residues were identified. (c) The top image shows the translucent electron density of supercomplex $\mathrm{I}_2/\mathrm{III}_2/\mathrm{IV}_2 + 2$ cytochrome *c*'s into which molecular models for each complex and Cyt c were docked. The bottom image was generated by rotating the top image 90° about a horizontal axis. The locations of the cytochrome *c*'s would permit them to rapidly shuttle electrons from complex III to complex IV (see Figure 12-19).

The unique phospholipid *cardiolipin* (diphosphatidyl glycerol) appears to play an important role in the assembly and function of these supercomplexes.

Generally found only in the inner mitochondrial membrane, cardiolipin, which normally composes about 20 percent of the lipids in the inner mitochondrial membrane, has been observed to bind to integral membrane proteins of the inner mitochondrial membrane (e.g., complexes I and II). Genetic and biochemical studies in yeast mutants in which cardiolipin synthesis is blocked have established that cardiolipin contributes to the formation and activity of mitochondrial supercomplexes; thus it has been called the glue that holds together the electron-transport chain, though the precise mechanism by which it does so remains to be defined. In addition, there is evidence that cardiolipin may influence the inner membrane's binding and permeability to protons and consequently the proton-motive force. When mitochondria are damaged, cardiolipin can move to the outer membrane, where it can participate in mitophagy. The role of cardiolipin can be seen in patients with Barth's syndrome, a human X-linked genetic disease

caused by defects in an enzyme that determines the structures of the acyl chains on cardiolipin. The reduction in the amounts of cardiolipin in these patients and its abnormal structure result in heart and skeletal muscle defects, growth retardation, and other abnormalities.

Reactive Oxygen Species Are By-Products of Electron Transport

Rather than being converted to water, about 1–2 percent of the oxygen metabolized by aerobic organisms is partially reduced to the superoxide anion radical ($O_2^{\bullet-}$, where the "dot" represents an unpaired electron). Radicals are atoms that have one or more unpaired electrons in an outer (valence) shell, or molecules that contain such an atom. Many, though not all, radicals are generally highly chemically reactive, altering the structures and properties of those molecules with which they react. The products of such reactions are often themselves radicals and can thus propagate a chain reaction that alters many additional molecules. Superoxide and other highly reactive oxygen-containing molecules, both radicals (e.g., $O_2^{\bullet-}$) and non-radicals (e.g., hydrogen peroxide, H_2O_2), are called **reactive oxygen species (ROS)**. ROS are of great interest because they can react with, and thus damage, many key biological molecules, including lipids (particularly unsaturated fatty acids and their derivatives), proteins, and DNA, and thus severely

interfere with their normal functions. At moderate to high levels, ROS contribute to what is often called *cellular oxidative stress* and can be highly toxic. Indeed, ROS are purposefully generated by body-defense cells (e.g., macrophages, neutrophils) to kill pathogens. In humans, excessive or inappropriate generation of ROS has been implicated in many diverse diseases, including heart failure, neurodegenerative diseases, alcohol-induced liver disease, and diabetes, as well as in aging. ■

Although there are several mechanisms for generating ROS in cells, their major source in eukaryotic cells is electron transport in the mitochondria (or in chloroplasts, as described below). Electrons passing through the mitochondrial electron-transport chain can have sufficient energy to reduce molecular oxygen (O_2) to form **superoxide anions** ($O_2^{\bullet -}$, Figure 12-24, *top*). This can occur, however, only when molecular oxygen comes in close contact with the reduced electron carriers (iron, FMN, $CoQH_2$) in the chain. Usually such contact is prevented by sequestration of the carriers within the proteins involved. However, there are some sites (particularly in complex I and $CoQ^{\bullet -}$, see Figure 12-18) and some conditions (e.g., high $NADH/NAD^+$ ratio in the matrix, high proton-motive force when ATP is not generated) when electrons can more readily leak out of the chain and reduce O_2 to $O_2^{\bullet -}$.

FIGURE 12-24 Generation and inactivation of toxic reactive oxygen species. Electrons from the electron-transport chains of mitochondria and chloroplasts, as well as some generated through other enzymatic reactions, reduce molecular oxygen (O_2), forming the highly reactive radical anion superoxide $(O_2{}^{\bullet -})$. Superoxide is rapidly converted by superoxide dismutase (SOD) to hydrogen peroxide (H_2O_2), which in turn can be converted by metal ions such as Fe^{2+} to hydroxyl radicals $(OH^\bullet)$ or inactivated to H_2O by enzymes such as catalase. Because of their high chemical reactivity, $O_2{}^{\bullet -}$, H_2O_2, $OH^\bullet$, and similar molecules are called *reactive oxygen species (ROS)*. They cause oxidative and free-radical damage to many biomolecules, including lipids, proteins, and DNA. This damage leads to cellular oxidative stress that can cause disease and, if sufficiently severe, can kill cells. In addition, ROS can function as intra- and intercellular signaling molecules.

The superoxide anion is an especially unstable, and thus reactive, ROS. Mitochondria have evolved several defense mechanisms that help protect against $O_2^{\bullet -}$ toxicity, including the use of enzymes that inactivate superoxide: first superoxide is converted to H_2O_2 by Mn-containing superoxide dismutase, called *SOD*, and then to H_2O by the enzyme catalase (see Figure 12-24). SOD and catalase are some of the fastest enzymes known so that they prevent the buildup of ROS. SOD is found within mitochondria and other cellular compartments. Hydrogen peroxide itself is an ROS that can diffuse readily across membranes and react with molecules throughout the cell. It can also be converted by certain metals, such as Fe^{2+}, into the even more dangerous hydroxyl radical ($OH^{\bullet}$). Thus cells depend on the inactivation of H_2O_2 by catalase and other enzymes, such as peroxiredoxin and glutathione peroxidase, which also detoxify the lipid hydroperoxide products formed when ROS react with unsaturated fatty acyl groups. Small-molecule antioxidant radical scavengers, such as vitamin E and α-lipoic acid, also protect against oxidative stress. Although in many cells catalase is located only in peroxisomes, in heart muscle cells it is found in mitochondria. This is not surprising because the heart is the most oxygen-consuming organ per gram in mammals.

As the rate of ROS production by mitochondria and chloroplasts reflects the metabolic state of these organelles (e.g., strength of proton-motive force, $NADH/NAD^+$ ratio), cells have developed ROS-sensing systems, such as ROS/redox-sensitive transcription

factors, to monitor the metabolic state of these organelles and respond accordingly — for example, by changing the rate of transcription of nuclear genes that encode organelle-specific proteins. Thus ROS such as H_2O_2 can function as a physiologically relevant intracellular, and even intercellular, signaling molecule. ROS have been reported to participate in cell processes as diverse as adaptation to low oxygen levels (hypoxia) and stress, growth factor and nutrient regulation of cell proliferation, cell differentiation, regulated cell death, and autophagy.

Experiments Using Purified Electron-Transport Chain Complexes Established the Stoichiometry of Proton Pumping

The multiprotein complexes of the electron-transport chain that are responsible for proton pumping have been identified by selectively extracting mitochondrial membranes with detergents, isolating each of the complexes in nearly pure form, and then preparing artificial phospholipid vesicles (liposomes) containing each complex. When an appropriate electron donor and electron acceptor are added to such liposomes, a change in the pH of the medium will occur if the embedded complex transports protons. Studies of this type as well as studies using membranes isolated from mitochondria indicate that NADH-CoQ reductase (complex I)

translocates four protons per pair of electrons transported, whereas cytochrome *c* oxidase (complex IV) translocates two protons per pair of electrons transported (see Figure 12-19).

Current evidence suggests that a total of 10 protons are transported from the matrix across the inner mitochondrial membrane for every electron pair that is transferred from NADH to O_2 (see Figure 12-19). Because succinate-CoQ reductase (complex II) does not transport protons, and because complex I is bypassed when the electrons come from succinate-derived $FADH_2$, only six protons are transported across the membrane for every electron pair that is transferred from this $FADH_2$ to O_2.

The Proton-Motive Force in Mitochondria Is Due Largely to a Voltage Gradient Across the Inner Membrane

The main result of the electron-transport chain is the generation of the proton-motive force, which is the sum of a transmembrane proton concentration (pH) gradient and an electric potential, or voltage gradient, across the inner mitochondrial membrane. The relative contributions of these two components to the total proton-motive force have been shown to depend on the permeability of the

membrane to ions other than H^+. A significant voltage gradient can develop only if the membrane is poorly permeable to other cations and to anions. Otherwise, anions would leak across the membrane from the matrix to the intermembrane space along with the protons and prevent a voltage gradient from forming. Similarly, if cations other than H^+ could leak across the membrane in a direction opposite to that of the H^+ (from the intermembrane space to the matrix), that leakage would counterbalance the positive charges delivered to the intermembrane space by the protons, short-circuiting voltage-gradient formation. Indeed, the inner mitochondrial membrane is poorly permeable to ions other than H^+. Thus proton pumping generates a voltage gradient that makes it energetically difficult for additional protons to move across the membrane because of charge repulsion. As a consequence, proton pumping by the electron-transport chain establishes a robust voltage gradient in the context of what turns out to be a rather small pH gradient.

Because mitochondria are much too small to be impaled with electrodes, the electric potential and pH gradient across the inner mitochondrial membrane cannot be directly measured. However, the electric potential can be measured indirectly by adding radioactive $^{42}K^+$ ions and a trace amount of valinomycin to a suspension of respiring mitochondria and measuring the amount of radioactivity that accumulates in the matrix. Although the inner membrane is normally impermeable to K^+, valinomycin is an

ionophore, a small lipid-soluble molecule that selectively binds a specific ion (in this case, K^+) and carries it across otherwise impermeable membranes. In the presence of valinomycin, $^{42}K^+$ equilibrates across the inner membrane of isolated mitochondria in accordance with the electric potential: the more negative the matrix side of the membrane, the more $^{42}K^+$ will be attracted to and accumulate in the matrix.

At equilibrium, the measured concentration of radioactive K^+ ions in the matrix, $[K^+{}_{\text{matrix}}]$, is about 500 times greater than that in the surrounding medium, $[K^+{}_{\text{out}}]$. Substitution of this value into the Nernst equation (see Chapter 11) shows that the electric potential E (in mV) across the inner membrane in respiring mitochondria is $-160\,\text{mV}$, with the matrix (inside) negative:

$$E = -59\ \log \frac{[K^+{}_{\text{matrix}}]}{[K^+{}_{\text{out}}]} = -59\ \log\ 500 = -160\,\text{mV}$$

Alternatively, the relative mitochondrial inner membrane potential can be measured using lipophilic cationic dyes such as tetramethylrhodamine methyl ester. The extent of accumulation of these fluorescent dyes in the mitochondrial matrix depends on the membrane potential and follows the Nernst equation. Various methods can be used to measure the fluorescence in the mitochondria, including flow cytometry, spectrofluorimetry, and quantitative fluorescence microscopy.

Researchers can measure the matrix (inside) pH by trapping pH-sensitive fluorescent dyes inside vesicles formed from the inner mitochondrial membrane, with the matrix side of the membrane facing inward. They can also measure the pH outside the vesicles (equivalent to the intermembrane space) and thus determine the pH gradient ($\Delta\mathrm{pH}$), which turns out to be about one pH unit. A difference of one pH unit represents a tenfold difference in H^+ concentration, so according to the Nernst equation, a pH gradient of one unit across a membrane is equivalent to an electric potential of 59 mV at 20 °C. Thus knowing the voltage and pH gradients, we can calculate the proton-motive force (pmf) as

$$\mathrm{pmf} = \Psi - \left(\frac{RT}{F} \times \Delta\mathrm{pH}\right) = \Psi - 59\,\Delta\mathrm{pH}$$

where R is the gas constant of $1.987\,\mathrm{cal/(degree \cdot mol)}$, T is the temperature (in degrees Kelvin), F is the Faraday constant $[23{,}062\,\mathrm{cal/(V \cdot mol)}]$, and Ψ is the transmembrane electric potential; Ψ and pmf are measured in millivolts. The electric potential Ψ across the inner membrane is $-160\,\mathrm{mV}$ (negative inside), and $\Delta\mathrm{pH}$ is equivalent to about 60 mV. Thus the total proton-motive force is $-220\,\mathrm{mV}$, with the transmembrane electric potential responsible for about 73 percent of the total.

KEY CONCEPTS OF SECTION 12.6

The Electron-Transport Chain and Generation of the Proton-Motive Force

- By the end of the citric acid cycle (stage II), much of the energy originally present in the covalent bonds of glucose and fatty acids has been converted into high-energy electrons in the reduced coenzymes NADH and $\mathrm{FADH_2}$. The energy from these electrons is used to generate the proton-motive force.
- In the mitochondrion, the proton-motive force is generated by coupling electron flow (from NADH and $\mathrm{FADH_2}$ to $\mathrm{O_2}$) to the energetically uphill transport of protons from the matrix across the inner membrane to the intermembrane space. This process, together with the synthesis of ATP from ADP and $\mathrm{P_i}$ driven by the proton-motive force, is called *oxidative phosphorylation*.
- As electrons flow from $\mathrm{FADH_2}$ and NADH to $\mathrm{O_2}$, they pass through multiprotein complexes. The four major complexes are NADH-CoQ reductase (complex I), succinate-CoQ reductase (complex II), $\mathrm{CoQH_2}$–cytochrome *c* reductase (complex III), and cytochrome *c* oxidase (complex IV) (see Figure 12-19).
- Each complex contains one or more electron-carrying prosthetic groups, which include iron-sulfur clusters, flavins, heme groups, and copper ions (see Table 12-3). Cytochrome *c*, which contains heme, and coenzyme Q (CoQ), a lipid-soluble small molecule, are mobile carriers that shuttle electrons between the complexes.
- Complexes I, III, and IV pump protons from the matrix into the intermembrane space. Complexes I and II reduce CoQ to $\mathrm{CoQH_2}$, which carries protons and high-energy electrons to complex III. The heme protein cytochrome *c* carries electrons from complex III to complex IV, which uses them to pump protons and reduce molecular oxygen to water.
- The high-energy electrons from NADH enter the electron-transport chain through complex I, whereas the high-energy electrons from $\mathrm{FADH_2}$ (derived from succinate in the citric acid cycle) enter the electron-transport chain through complex II. Additional electrons derived from $\mathrm{FADH_2}$ by the initial step of fatty acyl–CoA β-oxidation increase the supply of $\mathrm{CoQH_2}$ available for electron transport.
- The Q cycle allows four protons to be translocated per pair of electrons moving through complex III (see Figure 12-21).
- Each electron carrier in the chain accepts an electron or electron pair from a carrier with a less positive reduction potential and transfers the electron to a carrier with a more positive reduction potential. Thus the reduction potentials of electron carriers favor unidirectional, downhill, electron flow from NADH and $\mathrm{FADH_2}$ to $\mathrm{O_2}$ (see Figure 12-22).

- Within the inner mitochondrial membrane, electron-transport complexes assemble into supercomplexes held together by cardiolipin, a specialized phospholipid. Supercomplex formation may enhance the speed and efficiency of generation of the proton-motive force or play other roles.
- Reactive oxygen species (ROS) are toxic by-products of the electron-transport chain that can modify and damage proteins, DNA, and lipids. Specific enzymes (e.g., glutathione peroxidase, catalase) and small-molecule antioxidants (e.g., vitamin E) help protect against ROS-induced damage (see Figure 12-24). ROS can also be used as intracellular signaling molecules.
- A total of $10\,\mathrm{H}^+$ ions are translocated from the matrix across the inner membrane per electron pair flowing from NADH to O_2 (see Figure 12-19), whereas $6\,\mathrm{H}^+$ ions are translocated per electron pair flowing from FADH_2 to O_2.
- The proton-motive force is largely due to a voltage gradient across the inner membrane produced by proton pumping; the pH gradient plays a quantitatively less important role.

12.7 Harnessing the Proton-Motive Force to Synthesize ATP

The hypothesis that a proton-motive force across the inner mitochondrial membrane is the immediate source of energy for ATP synthesis was proposed in 1961 by Peter Mitchell. Virtually all researchers studying oxidative phosphorylation and photosynthesis initially rejected his proposal (called the *chemiosmotic hypothesis*). They favored a mechanism similar to the then well-elucidated substrate-level phosphorylation in glycolysis, in which chemical transformation of a substrate molecule (like phosphoenolpyruvate in glycolysis) is directly coupled to ATP synthesis. Despite intense efforts by a large number of investigators, however, compelling evidence for such a substrate-level phosphorylation–mediated mechanism was never observed.

Definitive evidence supporting Mitchell's hypothesis depended on developing and employing techniques to purify and reconstitute organelle membranes and membrane proteins. In one such experiment, outlined in Figure 12-25, vesicles made from chloroplast thylakoid membranes (equivalent to the inner membranes of mitochondria, we will discuss these later in this chapter) that contain the enzyme ATP synthase, were studied. This and other experiments demonstrated that ATP synthase is an ATP-generating enzyme and that ATP generation is dependent on proton movement down an electrochemical gradient across the membrane

in which the enzyme resided. It turns out that the protons actually move *through* the ATP synthase protein as they traverse the membrane.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 12-25 Synthesis of ATP by ATP synthase depends on a pH gradient across the membrane. Isolated chloroplast thylakoid vesicles

containing ATP synthase (F_0F_1 complexes) were equilibrated with a buffered solution at pH 4.0. When the pH in the thylakoid lumen reached 4.0, the vesicles were rapidly mixed with a solution at pH 8.0 containing ADP and P_i. A burst of ATP synthesis accompanied the transmembrane movement of protons driven by the 10,000-fold H^+ concentration gradient (10^{-4} M versus 10^{-8} M). In similar experiments using "inside-out" preparations of mitochondrial membrane vesicles, an artificially generated membrane electric potential, also resulted in ATP synthesis.

As we shall see, ATP synthase is a multiprotein complex that can be subdivided into two subcomplexes, called F_0 (containing the transmembrane portions of the complex) and F_1 (containing the globular portions of the complex that sit above the membrane and point into the matrix in mitochondria). Thus ATP synthase is often called the **F_0F_1 complex**; we will use the two terms interchangeably.

The Mechanism of ATP Synthesis Is Shared Among Bacteria, Mitochondria, and Chloroplasts

Eukaryotes use specialized membranes in intracellular organelles (mitochondria and chloroplasts) to make ATP. Of course, bacteria also need to make ATP, but they lack mitochondria or chloroplasts. Nevertheless, aerobic bacteria carry out oxidative phosphorylation by the same processes that occur in eukaryotic mitochondria and chloroplasts (Figure 12-26). Enzymes that catalyze the reactions of

both the glycolytic pathway and the citric acid cycle are present in the cytosol of bacteria; enzymes that oxidize NADH to NAD^+ and transfer the electrons to the ultimate acceptor O_2 reside in the bacterial plasma membrane. The movement of electrons through these membrane carriers is coupled to the pumping of protons out of the cell. The movement of protons back into the cell, down their concentration gradient through ATP synthase, releases energy that drives the synthesis of ATP. The bacterial ATP synthase (F_0F_1 complex) is essentially identical in structure and function to the mitochondrial and chloroplast ATP synthases, but is simpler to purify and study.

Why is the mechanism of ATP synthesis shared among both prokaryotic organisms and eukaryotic organelles? Primitive aerobic bacteria were probably the progenitors of both mitochondria and chloroplasts in eukaryotic cells (see Figure 12-7). According to this **endosymbiont hypothesis**, the inner mitochondrial membrane was derived from the bacterial plasma membrane, with its cytosolic face pointing toward what became the matrix of the mitochondrion. Similarly, in plants, a progenitor bacterium's plasma membrane became the chloroplast's thylakoid membrane, and its cytosolic face pointed toward what became the stromal space of the chloroplast (chloroplast structure and function will be described in Sections 12.7 and 12.8). In all cases, ATP synthase is positioned with the globular F_1 domain, which catalyzes ATP synthesis, on the cytosolic face of the membrane, so ATP is always formed on the cytosolic face (see

Figure 12-26). Protons always flow through ATP synthase from the membrane's exoplasmic face (facing the intermembrane space in mitochondria) to its cytosolic face (facing the matrix in mitochondria). This flow is driven by the proton-motive force. Invariably, the cytosolic face has a negative electric potential relative to the exoplasmic face.

FIGURE 12-26 ATP synthesis by chemiosmosis is similar in bacteria, mitochondria, and chloroplasts. In chemiosmosis, a proton-motive force generated by proton pumping across a membrane is used to power ATP synthesis. The mechanism and membrane orientation of the process are similar in bacteria, mitochondria, and chloroplasts. In each illustration, the membrane surface facing a shaded area is a cytosolic face; the surface facing an unshaded, white area is an exoplasmic face. Note that the cytosolic face of the bacterial plasma membrane, the matrix face of the inner mitochondrial membrane, and the stromal face of the thylakoid membrane are all equivalent. During electron transport, protons are always pumped from the cytosolic face to the exoplasmic face, creating a proton concentration gradient (exoplasmic face > cytosolic face) and an electric potential (negative cytosolic face and positive exoplasmic face) across the membrane. During the synthesis of ATP, protons flow in the reverse direction (down their electrochemical gradient) through an ATP synthase (F_0F_1 complex), which protrudes in a knob at the cytosolic face in all cases.

In addition to ATP synthesis, the proton-motive force across the bacterial plasma membrane is used to power other processes, including the uptake of nutrients such as sugars (using proton/sugar symporters) and the rotation of bacterial flagella. Chemiosmotic coupling thus illustrates an important principle introduced in our

discussion of active transport in Chapter 11: the membrane potential, the concentration gradients of protons (and other ions) across a membrane, and the phosphoanhydride bonds in ATP are equivalent and interconvertible forms of potential energy (also see Chapter 2). Indeed, ATP synthesis through ATP synthase can be thought of as active transport in reverse.

ATP Synthase Comprises $\mathbf{F_0}$ and $\mathbf{F_1}$ Multiprotein Complexes

With general acceptance of Mitchell's chemiosmotic mechanism, researchers turned their attention to the structure and operation of ATP synthase. The complex has two principal subcomplexes, F_0 and F_1, both of which are multimeric proteins (Figure 12-27a). The F_0 subcomplex contains three types of integral membrane proteins, designated **a, b**, and **c**. In bacteria and in yeast mitochondria, the most common subunit stoichiometry is $\mathbf{a}_1\mathbf{b}_2\mathbf{c}_{10}$, but the number of **c** subunits per subcomplex varies among different eukaryotes from 8 to 15. In all cases, the **c** subunits form a doughnut-shaped ring ("**c** ring") in the plane of the membrane. The one **a** and two **b** subunits are rigidly linked to one another, but not to the **c** ring, a critical feature of the protein to which we will return shortly. As you can see in Figure 12-27a, when the ATP synthase is operating, portions of the structure do not move (orange) and the rest (green) rotate together about an axis perpendicular to the plane of the membrane.

As we shall see, the flow of protons through the ATP synthase powers the rotation of the complex of the c, γ, and ε subunits that in turn drives the synthesis of ATP from ADP and P_i on the β subunits.

FIGURE 12-27 Structure of ATP synthase (the F_0F_1 complex) in the bacterial plasma membrane and mechanism of proton translocation across the membrane. (a) The F_0 membrane-embedded subcomplex of ATP synthase is built of three integral membrane proteins: one copy of **a**, two copies of **b**, and an average of ten copies of **c** arranged in a ring in the plane of the membrane. Two proton half-channels near the interfaces of subunit **a** with the **c** subunits mediate proton movement across the membrane (proton path is indicated by red arrows). Half-channel I allows protons to move one at a time from the exoplasmic medium (equivalent to intermembrane space in mitochondria) to the negatively charged side chain of Asp-61 in the center of a **c** subunit near the middle of the membrane. The proton-binding site in each **c** subunit is represented as a white circle with a blue "—" representing the negative charge on the side chain of Asp-61. Half-channel II permits protons to move from the Asp-61 of an adjacent **c** subunit into the cytosolic medium. In order for protons to move through the complex the c ring must rotate in the plane of the membrane, as shown by the detailed molecular structure of the **c** ring and a portion of the adjacent **a** subunit in Figure 12-30. The F_1 subcomplex of ATP synthase contains three copies each of subunits α and β, which form a hexamer resting atop the single rod-shaped γ

subunit, which is inserted into the **c** ring of F_0. The ε subunit is rigidly attached to the γ subunit and also to several of the **c** subunits. The δ subunit permanently links one of the α subunits in the F_1 subcomplex to the **b** subunit of F_0. Thus the F_0 **a** and **b** subunits and the F_1 δ subunit and $(\alpha\beta)_3$ hexamer form a rigid structure (orange) anchored in the membrane. During proton flow, the **c** ring and the attached F_1 ε and γ subunits rotate as a unit (green), causing conformational changes in the F_1 β subunits, leading to ATP synthesis. (b) Potential mechanism of proton translocation. Step **1**: A proton from the exoplasmic space enters half-channel I and moves toward the "empty" (unprotonated) Asp-61 proton-binding site. The negative charge (blue "−") on the unprotonated side chain Asp-61 is balanced, in part, by a positive charge on the side chain of Arg-210 (red "+"). Step **2**: The proton fills the empty proton-binding site and simultaneously displaces the positively charged Arg-210 side chain, which swings over to the filled proton-binding site on the adjacent **c** subunit (curved arrow). As a consequence, the proton bound at that adjacent site is displaced. Step **3**: The displaced adjacent proton moves through half-channel II and is released into the cytosolic space, leaving an empty proton-binding site on Asp-61. Step **4**: Counterclockwise rotation of the entire **c** ring moves the "empty" **c** subunit over half-channel I. Step **5**: The process is repeated. See M. J. Schnitzer, 2001, *Nature* **410**:878–881; P. D. Boyer, 1999, *Nature* **402**:247–249; and C. von Ballmoos, A. Wiedenmann, and P. Dimroth, 2009, *Annu. Rev. Biochem.* **78**:649–672.

The F_1 subcomplex is a water-soluble complex of five distinct polypeptides with the composition $\alpha_3\beta_3\gamma\delta\varepsilon$ that is normally firmly bound to the **a** subunit of the F_0 subcomplex at the surface of the membrane. The lower end of the rodlike γ subunit of the F_1 subcomplex is a coiled coil that fits into the center of the **c**-subunit ring of F_0 and appears rigidly attached to it. Thus when the **c**-subunit ring rotates, the rodlike γ subunit rotates with it. The F_1 ε subunit is rigidly attached to γ and also forms tight contacts with several of the **c** subunits of F_0. The α and β subunits are responsible for the overall globular shape of the F_1 subcomplex and associate in

alternating order to form a hexamer, αβαβαβ, or $(\alpha\beta)_3$, which rests atop, but is not rigidly attached to the single long γ subunit. The F_1 δ subunit is permanently linked to one of the F_1 α subunits and also binds to the **b** subunit of F_0. Thus the **a** and **b** subunits of the F_0 subcomplex and the δ subunit and $(\alpha\beta)_3$ hexamer of the F_1 subcomplex form a rigid structure anchored in the membrane. The rodlike **b** subunits form a "stator" that prevents the $(\alpha\beta)_3$ hexamer from moving while it rests on the γ subunit, whose rotation, together with that of the ε subunit and the **c**-subunit ring of F_0, plays an essential role in the ATP synthesis mechanism described below.

When ATP synthase is embedded in a membrane, the F_1 subcomplex forms a knob that protrudes from the cytosolic face (the matrix face in the mitochondrion). Because F_1 separated from membranes is capable of catalyzing ATP hydrolysis (ATP conversion to ADP plus P_i) in the absence of the F_0 subcomplex, it has been called the *F_1 ATPase*; however, its function in cells is the reverse, to synthesize ATP. ATP hydrolysis is a spontaneous process ($\Delta G < 0$); thus energy is required to drive the ATPase in reverse and generate ATP.

Rotation of the $F_1\gamma$ Subunit, Driven by Proton Movement Through F_0, Powers ATP Synthesis

Each of the three β subunits in the globular F_1 subcomplex of F_0F_1 can bind ADP and P_i and catalyze the endergonic synthesis of ATP when coupled to the flow of protons from the exoplasmic medium (the intermembrane space in the mitochondrion) to the cytosolic (matrix) medium. However, the energetic coupling of proton flow and ATP synthesis does not take place in the same portions of the protein, because the nucleotide-binding sites on the β subunits of F_1, where ATP synthesis occurs, are 9–10 nm from the surface of the membrane-embedded portion of F_0 through which the protons flow. The most widely accepted model for ATP synthesis by the F_0F_1 complex — the **binding-change mechanism** — posits an indirect, mechanical coupling (Figure 12-28).

FIGURE 12-28 The binding-change mechanism of ATP synthesis from ADP and P_i. This view is looking up at F_1 from the membrane surface (see Figure 12-27). As the γ subunit

rotates by 120° in the center, each of the otherwise identical β subunits alternates among three conformational states (O, open, with oval representation of the nucleotide binding site; L, loose, with a rectangular binding site; T, tight, with a triangular site) that differ in their binding affinities for ATP, ADP, and P_i. To make it easier for you to follow the reactions, the three different sets of $ADP + P_i$ (and their product ATP) are colored red, blue, or green. The cycle begins (*upper left*) when ADP and P_i bind loosely to one of the three β subunits (here, arbitrarily designated β_1) whose nucleotide-binding site is in the O (open) conformation. Proton flux through the F_0 portion of the protein powers a 120° rotation of the γ subunit (relative to the fixed β subunits) (step **1**). This causes the rotating γ subunit, which is asymmetric, to push against each of the three β subunits in different ways, resulting in distinct conformational changes in each β subunit. In step **1** this results in an increase in the binding affinity of the β_1 subunit for ADP and $P_i(O \rightarrow L)$, an increase in the binding affinity of the β_3 subunit for ADP and P_i that were previously bound $(L \rightarrow T)$, and a decrease in the binding affinity of the β_2 subunit for a previously bound ATP $(T \rightarrow O)$, causing release of the bound ATP. Step **2**: Without additional rotation, the ADP and P_i in the T site (here, in the β_3 subunit) form ATP, a reaction that does not require an input of additional energy due to the special environment in the active site of the T state. At the same time, a new ADP and P_i bind loosely to the unoccupied O site on β_2. Step **3**: Proton flux powers another 120° rotation of the γ subunit, consequent conformational changes in the binding sites $(L \rightarrow T, O \rightarrow L, T \rightarrow O)$, and release of ATP from β_3. Step **4**: Without additional rotation, the ADP and P_i in the T site of β_1 form ATP, and additional ADP and P_i bind to the unoccupied O site on β_3. The process continues with rotation (step **5**) and ATP formation (step **6**) until the cycle is complete, with three ATPs having been produced for every 360° rotation of γ. See P. Boyer, 1989, *FASEB J.* **3**:2164–2178; Y. Zhou et al., 1997, *Proc. Natl. Acad. Sci. USA* **94**:10583–10587; and M. Yoshida, E. Muneyuki, and T. Hisabori, 2001, *Nat. Rev. Mol. Cell Biol.* **2**:669–677.

According to this mechanism, energy released by the downhill movement of protons through F_0 directly powers rotation of the **c**-subunit ring together with its rigidly attached γ and ε subunits (see Figure 12-27a). The γ subunit is a nonsymmetrical, rotating shaft, similar to a camshaft in a car engine, whose **c** ring–driven rotation

within the center of the static $(\alpha\beta)_3$ hexamer of F_1 causes it to push sequentially against each of the β subunits. The mechanical force exerted on the β subunits induces cyclical changes in their conformations and drives the conversion of ADP and P_i to ATP in the active site of each β subunit. As schematically depicted in a view of the bottom of the $(\alpha\beta)_3$ hexamer's globular structure in Figure 12-28, rotation of the γ subunit relative to the fixed $(\alpha\beta)_3$ hexamer causes the nucleotide-binding, active site of each β subunit to cycle through three conformational states in the following order:

1. An O (open) state that binds ATP very poorly and ADP and P_i weakly
2. An L (loose) state that binds ADP and P_i more strongly but cannot bind ATP
3. A T (tight) state that binds ADP and P_i so tightly that they spontaneously react and form ATP

In the T state, the ATP produced is bound so tightly that it cannot readily dissociate from the site — it is trapped until further rotation of the γ subunit returns that β subunit to the O state, thereby releasing ATP and beginning the cycle again. ATP or ADP also binds to regulatory or allosteric sites on the three α subunits; this binding modifies the rate of ATP synthesis according to the level of ATP and ADP in the matrix, but is not directly involved in the catalytic step that synthesizes ATP from ADP and P_i.

Several types of evidence support the binding-change mechanism. First, biochemical studies showed that on isolated F_1 particles one of the three β subunits can tightly bind ADP and P_i and then form ATP, which remains tightly bound. The measured ΔG for this reaction is near zero, indicating that once ADP and P_i are bound to the T state of a β subunit, they spontaneously form ATP. Importantly, dissociation of the bound ATP from the β subunit on isolated F_1 particles occurs extremely slowly. This finding suggested that dissociation of ATP would have to be powered by a conformational change in the β subunit, which in turn would be due to **c**-ring rotation caused by proton movement.

A second line of evidence comes from x-ray crystallographic analysis of the $(\alpha\beta)_3$ hexamer, which yielded a striking conclusion: although the three β subunits are identical in sequence and overall structure, the ADP/ATP-binding sites have different conformations in each subunit. The most reasonable conclusion was that the three β subunits cycle in an energy-dependent reaction between three conformational states (O, L, T), in which the nucleotide-binding site has substantially different structures.

In other studies, intact F_0F_1 complexes were treated with chemical cross-linking agents that covalently linked the γ and ε subunits and the **c**-subunit ring. The observation that such treated complexes could synthesize ATP or use ATP to power proton pumping indicates that the cross-linked proteins normally rotate together.

Finally, rotation of the γ subunit relative to the fixed $(\alpha\beta)_3$ hexamer, as proposed in the binding-change mechanism, was observed directly by microscopy in the clever experiment depicted in Figure 12-29. A fluorescently labeled actin filament was attached to the γ subunit of F_1; the F_1-mediated ATP hydrolysis then caused the filament to rotate like a propeller in 120° steps. In one modification of this experiment in which tiny gold particles, rather than an actin filament, were attached to the γ subunit, rotation rates of 134 revolutions per second were observed. Hydrolysis of three ATPs, which you recall is the reverse reaction catalyzed by the same enzyme, is thought to power one revolution; this result is close to the experimentally determined rate of ATP hydrolysis by F_0F_1 complexes: about 400 ATPs per second. These and similar experiments established that the γ subunit, along with the attached **c** ring and ε subunit, does indeed rotate, thereby driving the conformational changes in the β subunits that are required for the binding of ADP and P_i, followed by synthesis and subsequent release of ATP.

EXPERIMENTAL FIGURE 12-29 The γ subunit of the F_1 subcomplex rotates relative to the $(\alpha\beta)_3$ hexamer. F_1 subcomplexes were engineered to contain β subunits with an additional His-6 sequence, which causes them to adhere to a glass plate coated with a metal reagent that binds polyhistidine. The γ subunit in the engineered F_1 subcomplexes was linked covalently to a fluorescently labeled actin filament. When viewed in a fluorescence microscope, the actin filament was seen to rotate counterclockwise in discrete 120° steps in the presence of ATP due to ATP hydrolysis by the β subunits. See H. Noji et al., 1997, *Nature* **386**: 299–302; and R. Yasuda et al., 1998, *Cell* **93**:1117–1124.

Multiple Protons Must Pass Through ATP Synthase to Synthesize One ATP

A simple calculation indicates that the passage of more than one proton across the membrane and down the electrochemical

gradient is required to synthesize one molecule of ATP from ADP and P_i. Although the ΔG for this reaction under standard conditions is $+7.3\,\text{kcal/mol}$, at the concentrations of reactants in the mitochondrion, ΔG is probably higher ($+10$ to $+12\,\text{kcal/mol}$). We can calculate the amount of free energy released by the passage of 1 mol of protons down an electrochemical gradient of 220 mV (0.22 V) from the Nernst equation, setting $n = 1$ and measuring ΔE in volts:

$$\begin{aligned}\Delta G(\text{cal/mol}) &= -nF\Delta E = -(23{,}062\,\text{cal}\cdot V^{-1}\cdot \text{mol}^{-1})\Delta E \\ &= (23{,}062\,\text{cal}\cdot V^{-1}\cdot \text{mol}^{-1})(0.22\,\text{V}) \\ &= 5074\,\text{cal/mol, or } -5.1\,\text{kcal/mol}\end{aligned}$$

Because the downhill movement of 1 mol of protons releases just over 5 kcal of free energy, the passage of at least two protons is required for synthesis of each molecule of ATP from ADP and P_i.

F_0 c Ring Rotation Is Driven by Protons Flowing Through Transmembrane Channels

Each copy of the **c** subunit contains two membrane-spanning α helices that form a hairpin-like structure (Figure 12-30a, *right*). An aspartate residue, Asp-61 (*E. coli* ATP synthase numbering), in the center of one of these helices in each **c** subunit is thought to play a key role in proton movement by binding and releasing protons as

they traverse the membrane. Chemical modification of this aspartate by the poison dicyclohexylcarbodiimide, or its mutation to alanine, specifically blocks proton movement through F_0. According to one current model, the protons traverse the membrane via two staggered half-channels, I and II (see Figure 12-27a and b). They are called *half-channels* because each extends only halfway across the membrane; the intramembrane termini of the channels are at the level of Asp-61 in the middle of the membrane. Half-channel I is open only to the exoplasmic face, and half-channel II is open only to the cytosolic face. Prior to rotation, each of the Asp-61 carboxylate side chains in the **c** subunits is bound to a proton, except for that on the **c** subunit in contact with half-channel I. The negative charge on that unprotonated carboxylate (the "empty" proton-binding site; see Figure 12-27b, *bottom*) is neutralized by interaction with the positively charged side chain of Arg-210 from the **a** subunit. Proton translocation across the membrane begins when a proton from the exoplasmic medium (intermembrane space in mitochondria) moves upward through half-channel I (see Figure 12-27b, step **1**). As that proton moves into the empty proton-binding site, it displaces the Arg-210 side chain, which swings toward the filled proton-binding site of the adjacent **c** subunit in contact with half-channel II (step **2**). As a consequence, the positive side chain of Arg-210 displaces the proton bound to Asp-61 of the adjacent **c** subunit. This displaced proton is now free to travel up half-channel II and out into the cytosolic medium (matrix in mitochondria) (step **3**). Thus when one proton entering from half-channel I binds to the **c** ring, a

different proton on an adjacent **c** subunit is released to the opposite side of the membrane via half-channel II. Rotation of the entire **c** ring due to thermal/Brownian motion (step **4**) then allows the newly unprotonated **c** subunit to move into alignment above half-channel I as an adjacent, protonated **c** subunit rotates in to take its place under half-channel II. The entire cycle is then repeated (step **5**) as additional protons move down their electrochemical gradient from the exoplasmic medium to the cytosolic medium. During each partial rotation (360° divided by the number of **c** subunits in the ring), the **c** ring rotation is ratcheted, in that net movement of the ring occurs in only one direction. The energy driving the protons across the membrane, and thus the rotation of the **c** ring, comes from the electrochemical gradient across the membrane. If the direction of proton flow is reversed, which can be done by experimentally reversing the direction of the proton gradient and the proton-motive force, the direction of **c** ring rotation is reversed.

Because the γ subunit of F_1 is tightly attached to the **c** ring of F_0, rotation of the **c** ring associated with proton movement causes rotation of the γ subunit. According to the binding-change mechanism, a 120° rotation of γ powers synthesis of one ATP (see Figure 12-28). Thus complete rotation of the **c** ring by 360° would generate three ATPs. In *E. coli*, where the F_0 composition is $\mathbf{a}_1\mathbf{b}_2\mathbf{c}_{10}$, movement of 10 protons drives one complete rotation and thus synthesis of three ATPs. This value is consistent with experimental data on proton flux during ATP synthesis, providing indirect support

for the model coupling proton movement to **c** ring rotation depicted in Figure 12-27. The F_0 from mammals contains 8 **c** subunits per ring. The F_0 from chloroplasts contains 14 **c** subunits per ring, and movement of 14 protons would be needed for synthesis of three ATPs. Why these otherwise similar F_0F_1 complexes have evolved to have different H^+:ATP ratios is not clear.

High-resolution electron microscopic tomography (Figure 12-30) has provided additional insights into the structure of the **c** ring/**a** subunit interface and other features of F_0F_1 structure and function. The experiments were performed using F_0F_1 either dissolved in detergent, then incorporated into artificial phospholipid bilayers, or in isolated mitochondrial membranes. Figures 12-30a and b show two views of the two membrane-spanning α helices in each copy of the **c** subunit (green) that together form the **c** ring. In a portion of the **a** subunit (orange), a bundle of four α helices that are almost parallel to and embedded within the inner mitochondrial membrane forms the interface with the **c** ring and positions the side chain of the **a** subunit's Arg 210 adjacent to the **c** ring so that it can mediate proton displacement from Asp 61 as shown in Figure 12-27. The **c** ring/**a** subunit interface also forms the two proton half-channels through which protons flow out of the intermembrane space (red arrow), around the **c** ring (black arrows in Figure 12-30b), and then out into the matrix (red arrow). Each F_0F_1 monomer bends the membrane by approximately 43° (Figure 12-30c). The monomers dimerize to impart high membrane curvature ($\sim 86^\circ$) and then align

in long rows, contributing to the formation of the edges and tips of the pancake-like (flat) and tubular cristae (Figure 12-30d and e, also see Figure 12-6a).

EXPERIMENTAL FIGURE 12-30 High-resolution electron microscopy-based mechanism of proton translocation and bending of cristae membranes by ATP synthase. (a) and (b) The interface between the **c** ring (green) and **a** subunit (orange) of detergent-solubilized mitochondrial ATP synthase from the alga *Polytomella* sp., imaged by single-particle cryoelectron microscopy ($\sim 0.62\ \mathrm{nm}$ resolution), is shown (a) from within the plane of the inner mitochondrial membrane (side view) and (b) after a 90° rotation (top view). The movement of protons through half-channels I and II and the rotation of the **c** ring are described in detail in Figure 12-27. (a) Cross section through the **c** ring (right) shows that

each **c** subunit is a transmembrane helical hairpin — two adjacent transmembrane α helices connected by a short nonhelical linker on the matrix side of the membrane. The negative side chain of the **c** subunit's Asp61 in the middle of the membrane is thought to both serve as a binding site for translocating protons and interact with the side chain of the **a** subunit's Arg210. (c) A model of the bovine heart mitochondrial ATP synthase dimer is based on cryoelectron tomography and electron crystallographic image processing from crystalline ATP synthase in artificial membranes. Each $\mathrm{F_0F_1}$ monomer bends the membrane by ~ 43° toward the intermembrane space (IMS), resulting in dimers bending the membrane by ~ 86°. The rotating **c** ring and γ and ε subunits are colored green, and the remaining static portions of the enzyme are shown in orange. (d) Cryoelectron tomographic image of frozen membranes from purified *Saccharomyces cerevisiae* (yeast) mitochondria. The surfaces of the ATP synthase complexes (yellow) and the membrane (gray) show that the enzymes dimerize as in (c) and align into long rows that bend the membranes into characteristic tubular and flat, pancake-like cristae. (e) Cartoon illustrating the topological relationships of the rows of ATP synthase dimers (orange and green) on the curved edge of a crista to other components of the inner membrane (electron transport supercomplexes $(\mathrm{I_2/III_2/IV_2})$ and the crista junction complex MICOS, gray) and the outer membrane (SAM and Tom complexes, gray) that link MICOS to the outer membrane. The cycling of protons (red spheres) from the matrix through the electron-transport chain to the inner membrane space and then back into the matrix via ATP synthase is indicated by black arrows. The relative sizes of the proteins and membrane bilayers are not drawn to scale.

ATP-ADP Exchange and Phosphate Transport Across the Inner

Mitochondrial Membrane Are Required to Supply ADP and Phosphate for ATP Synthesis

It is estimated that at any one time an adult human contains about 50 g of ATP, yet that same individual must hydrolyze 65 kg of ATP per day. Thus mitochondria must generate 65 kg of ATP/day per person from ADP and P_i and transport most of that ATP out of the matrix where it is generated (Figures 12-11 and 12-26) so that it can be used elsewhere in the cells. Clearly large amounts of ADP and P_i must be transported into the matrix to sustain ATP synthesis. This transport is mediated by two proteins in the inner membrane (Figure 12-31): a *phosphate* (P_i, HPO_4^{2-}) *transporter*, which mediates the import of one HPO_4^{2-} coupled to either the import of one proton or the export of one OH^- (export of OH^- shown in the figure and we will assume phosphate/hydroxyl exchange below), and an *ATP/ADP exchanger* (see Figure 12-31). The 30,000-Da ATP/ADP exchanger makes up 10–15 percent of the protein in the inner mitochondrial membrane, so it is one of the more abundant mitochondrial proteins. Both of these transporters are members of the SLC25 family of mitochondrial inner membrane transporters. The SLC25 transporters each have six transmembrane α-helices and use the alternating access mechanism (see Figure 11-6) to move their substrates across the inner mitochondrial membrane. The P_i and ATP/ADP transporters together produce an influx into the matrix

of one ADP^{3-} and one P_i^{2-} and an efflux of one ATP^{4-} together with one OH^-. Each OH^- transported outward combines with a proton, translocated during electron transport to the intermembrane space, to form H_2O. Thus proton translocation via electron transport together with the relatively high matrix concentration of ATP under normal circumstances drive the overall reaction in the direction of ATP export and ADP and P_i import. In adult humans, each ATP molecule is recycled across the inner membrane about 1300 times a day.

FIGURE 12-31 The phosphate and $\mathbf{ATP/ADP}$ transport system in the inner mitochondrial membrane. The coordinated action of two transporters (purple and green ovals), which results in the uptake into the matrix of one ADP^{3-} and one $HPO_4{}^{2-}$ in exchange for one ATP^{4-} and one hydroxyl, is powered by the outward translocation of one proton (mediated by the proteins of the electron-transport chain, blue rectangle) during electron transport. Red arrows indicate that movement of a proton and hydroxyl out of the matrix results in export of H_2O. The outer membrane is not shown here because it is permeable to molecules smaller than 5000 Da.

Because some of the protons translocated out of the mitochondrial matrix during electron transport provide the power (by combining with the exported OH^-) for the phosphate transport and help neutralize the extra negative charge carried into the matrix on ATP relative to ADP, fewer protons are available for ATP synthesis. It is estimated that for every four protons translocated across the inner membrane during electron transport, about three are used to synthesize one ATP molecule and one is used to power the export of ATP from the mitochondrion in exchange for ADP and P_i. This expenditure of energy from the proton concentration gradient to export ATP from the mitochondrion in exchange for ADP and P_i ensures a high ratio of ATP to ADP in the cytosol, where hydrolysis of the high-energy phosphoanhydride bond of ATP is used to power many energy-requiring reactions.

Studies of what turned out to be ATP/ADP exchanger activity were first recorded about 2000 years ago, when Dioscorides (~AD 40–90) described the effects of a poisonous herb from the thistle *Atractylis gummifera*. The same agent is found in the traditional Zulu multipurpose herbal remedy *impila* (*Callilepis laureola*), although this herb has caused numerous poisonings. The active agent, atractyloside, inhibits the ATP/ADP transporter and thus inhibits oxidative phosphorylation of extramitochondrial ADP, but not intramitochondrial (matrix) ADP. Atractyloside, which shows the importance of the ATP/ADP transporter, continues to be used to study the mechanism by which this transporter functions.

Dioscorides lived near Tarsus, at the time a province of Rome in southeastern Asia Minor, in what is now Turkey. His five-volume *De Materia Medica* (*The Materials of Medicine*) "on the preparation, properties, and testing of drugs" described the medicinal properties of about 1000 natural products. For about 1600 years, it was the basic reference in medicine for using drugs from northern Europe to the Indian Ocean, comparable to today's *Physicians' Desk Reference*. ■

The Rate of Mitochondrial Oxidation Normally Depends on ADP Levels

If intact isolated mitochondria are provided with NADH (or a source of $FADH_2$ such as succinate) plus O_2 and P_i, but not ADP, the oxidation of NADH and the reduction of O_2 rapidly cease as the amount of endogenous ADP is depleted by ATP formation. If ADP is then added, the oxidation of NADH is rapidly restored. Thus mitochondria can oxidize $FADH_2$ and NADH only as long as there is a source of ADP and P_i to generate ATP. This phenomenon, termed **respiratory control**, occurs because oxidation of NADH and succinate ($FADH_2$) is obligatorily coupled to proton transport across the inner mitochondrial membrane. If the resulting proton-motive force is not dissipated during the synthesis of ATP from ADP and P_i (or during other energy-requiring processes), both the transmembrane proton concentration gradient and the membrane electric potential will increase to very high levels. At this point,

pumping of additional protons from the matrix across the inner membrane requires so much energy that it eventually ceases, blocking the coupled oxidation of NADH and other substrates.

Mitochondria in Brown Fat Use the Proton-Motive Force to Generate Heat

Brown-fat tissue, whose color is due to the presence of abundant mitochondria, is specialized for the generation of heat. In contrast, *white-fat tissue* is specialized for the storage of fat and contains relatively few mitochondria.

The inner membranes of brown-fat mitochondria contain a protein called **uncoupling protein 1 (UCP1)**, a protein that functions as an **uncoupler** of oxidative phosphorylation and ATP generation. UCP1 is one of several uncoupling proteins (UCPs) found in most eukaryotes (but not in fermentative yeasts). As with the ATP/ADP exchanger and the phosphate transporter, UCPs are members of the SLC25 family of transporters. UCP1, which requires a bound fatty acid molecule as a cofactor, functions as an intermembrane space-to-matrix proton transporter. Fatty-acid-containing UCP1 dissipates the proton-motive force by rendering the inner mitochondrial membrane permeable to protons. As a consequence, the energy released by NADH oxidation in the electron-transport chain and used to transport protons out of the matrix is not available to be

used to synthesize ATP via ATP synthase. Instead, when protons move back into the matrix down their concentration gradient via UCP1, the energy is released as heat. UCP1 is a proton transporter, not a proton channel, and shuttles protons across the membrane at a rate that is 1-million-fold slower than that of typical ion channels (see Figure 11-3). Certain small-molecule poisons also function as uncouplers by rendering the inner mitochondrial membrane permeable to protons. One example is the lipid-soluble chemical 2,4-dinitrophenol (DNP), which can reversibly bind to and release protons and shuttle them across the inner membrane from the intermembrane space into the matrix. Remarkably, when a fatty acid binds to the ATP/ADP exchanger, this transporter can also transport protons from the matrix to the intermembrane space and thus, just like UCP1, uncouple oxidative phosphorylation that generates a proton-motive force and ATP synthesis.

Environmental conditions regulate the amount of UCP1 in brown-fat mitochondria. For instance, when rats adapt to cold temperatures, the ability of their tissues to generate heat is increased by the induction of UCP1 synthesis. In cold-adapted animals, UCP1 may constitute up to 15 percent of the total protein in the inner membranes of brown-fat mitochondria.

In the newborn human, UCP1 expression by brown-fat mitochondria is vital to survival, as it is in hibernating mammals. In adult humans there is usually little brown fat, which is located in the

neck, clavicle, and other sites. The amounts of human brown fat are significantly increased upon exposure to cold. In fur seals and other animals naturally acclimated to the cold, muscle-cell mitochondria contain UCP1; as a result, much of the proton-motive force is used for generating heat, thereby maintaining body temperature. Detailed analyses of the biochemical properties and developmental origins of thermogenic fat cells have uncovered the existence of at least two subtypes of such cells: classic brown-fat cells that develop from precursor cells also used to generate skeletal muscle cells, and *beige-fat cells* whose detailed properties (gene expression pattern, responses to hormonal signals) differ from those of brown-fat cells and are formed from white-fat cells or their progenitors. Thus there are three types of fat: brown, white, and beige. Further characterization of beige-fat cells and their influence on normal metabolism and disease may lead to new approaches to treat or prevent some metabolic disorders.

KEY CONCEPTS OF SECTION 12.7

Harnessing the Proton-Motive Force to Synthesize ATP

- The chemiosmotic hypothesis, proposed by Peter Mitchell, states that a proton-motive force across the inner mitochondrial membrane is the immediate source of energy for ATP synthesis.
- Bacteria, mitochondria, and chloroplasts all use the same chemiosmotic mechanism and a similar ATP synthase to generate ATP (see Figure 12-26).
- ATP synthase (also called the F_0F_1 *complex*) catalyzes ATP synthesis as protons flow through the inner mitochondrial membrane (the plasma membrane in bacteria) down their electrochemical proton gradient.

- F_0 contains a ring of 8–14 **c** subunits, depending on the organism, that is rigidly linked to the rod-shaped γ subunit and the ε subunit of F_1. These subunits rotate during ATP synthesis. Resting atop the γ subunit is the hexameric knob of F_1 $[(\alpha\beta)_3]$, which protrudes into the mitochondrial matrix (cytosol in bacteria). The three β subunits are the sites of ATP synthesis (see Figure 12-27 and 12-30a and b).
- Rotation of the asymmetic F_1 γ subunit, which is inserted in the center of the nonrotating $(\alpha\beta)_3$ hexamer, leads to sequential changes in the conformation of the nucleotide-binding sites in the three F_1 β subunits (see Figure 12-28). By means of this binding-change mechanism, the β subunits bind ADP and P_i, condense them to form ATP, and then release the ATP. Three ATPs are made for each revolution of the rigid complex of the **c** ring and γ and ε subunits.
- Movement of protons across the membrane via two half-channels at the interface of the F_0 **a** subunit and the **c** ring powers rotation of the **c** ring with its attached F_1 ε and γ subunits.
- The F_0F_1 complex bends the inner mitochondrial membrane, contributing to its characteristic high curvature and to the tubular and pancake-like structures of the cristae (see Figure 12-30c, d, and e).
- The proton-motive force also powers the uptake of P_i and ADP from the cytosol in exchange for mitochondrial ATP and OH^-, thus reducing the energy available for ATP synthesis. The ATP/ADP antiporter that participates in this exchange is one of the most abundant proteins in the inner mitochondrial membrane (see Figure 12-31).
- Continued mitochondrial oxidation of NADH and reduction of O_2 are dependent on sufficient ADP being present in the matrix. This phenomenon, termed *respiratory control*, is an important mechanism for coordinating oxidation and ATP synthesis in mitochondria.
- In brown fat, the inner mitochondrial membrane contains the uncoupler protein UCP1, a proton transporter that dissipates the proton-motive force into heat. Certain chemicals also function as uncouplers (e.g., DNP) and have the same effect, uncoupling oxidative phosphorylation from electron transport. There are two distinct types of thermogenic fat cells: brown-fat and beige-fat cells.

12.8 Chloroplasts and Photosynthesis

We now shift our attention to photosynthesis, the second key process for synthesizing ATP. In plants, photosynthesis occurs in chloroplasts, large organelles found mainly in leaf cells. During photosynthesis, chloroplasts capture the energy of sunlight, convert it into chemical energy in the form of ATP and NADPH, and then use this energy to synthesize complex carbohydrates out of carbon dioxide and water. It is estimated that annually photosynthesis on earth results in the conversion of 104.9×10^{15} g of carbon from CO_2 into organic molecules. In cyanobacteria, algae, and plants photosynthesis also generates molecular oxygen from water. The principal carbohydrates produced are polymers of hexose (six-carbon) sugars: sucrose, a glucose-fructose disaccharide (see Figure 2-19), and **starch**, a mixture of two types of large, insoluble glucose polymers called *amylose* and *amylopectin*. Starch is the primary storage carbohydrate in plants (Figure 12-32). Starch is synthesized and stored in the chloroplast. Sucrose is synthesized in the leaf cytosol from three-carbon precursors generated in the chloroplast; it is transported to non-photosynthetic (nongreen) plant tissues (e.g., roots and seeds), which metabolize it for energy by the pathways described in the previous sections.

FIGURE 12-32 Structure of starch. The large glucose polymer and the disaccharide sucrose (see Figure 12-15) are the principal end products of photosynthesis. Both are built of six-carbon sugars (hexoses).

Thylakoid Membranes in Chloroplasts Are the Sites of Photosynthesis in Plants

Chloroplasts are lens-shaped organelles with a diameter of approximately 5 μm and a width of approximately 2.5 μm (Figure 12-33 and 1-20). They contain >2500 different proteins, 95 percent of which are encoded in the nucleus, made in the cytosol, imported into the organelle, and then transported to their appropriate membrane or space (see Chapter 13). Chloroplasts are bounded by two membranes, which do not contain chlorophyll and do not

participate directly in the generation of ATP and NADPH driven by light (Figures 12-33 and 12-34). Like that of mitochondria, the outer membrane of chloroplasts contains porins and thus is permeable to metabolites of small molecular weight. The inner membrane forms a permeability barrier that contains transport proteins for regulating the movement of metabolites into and out of the organelle.

Unlike mitochondria, chloroplasts contain a third membrane — the **thylakoid membrane** — on which the light-driven generation of ATP and NADPH occurs. The chloroplast thylakoid membrane is believed to constitute a single sheet that forms numerous small, interconnected flattened structures, the **thylakoids**, which are commonly arranged in stacks termed *grana* (see Figure 12-33). The spaces within all the thylakoids constitute a single continuous compartment, the **thylakoid lumen** (see Figure 12-34). The thylakoid membrane contains a number of integral membrane proteins; bound to these are several important prosthetic groups and light-absorbing pigments, most notably chlorophylls. Starch synthesis and storage occurs in the **stroma**, the aqueous compartment between the thylakoid membrane and the inner membrane. In photosynthetic bacteria, extensive invaginations of the plasma membrane form a set of internal membranes, also termed *thylakoid membranes*, where photosynthesis occurs.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freem

FIGURE 12-33 Structure of leaf and chloroplast. Like mitochondria, plant chloroplasts are bounded by two membranes separated by an intermembrane space. Photosynthesis occurs on a third membrane, the thylakoid membrane, which is surrounded by the inner membrane and which forms a series of flattened vesicles (thylakoids) that enclose a luminal space. The green color of plants is due to the color of chlorophyll and carotenoids, all of which is located within the thylakoid membrane. A granum is a stack of adjacent thylakoids. The stroma is the space between the inner membrane and the thylakoids.

[From Katherine Esau, D-120, Special Collections, University of California Library, Davis.]

Chloroplasts Contain Large DNAs Often Encoding More Than a Hundred Proteins

Like mitochondria, chloroplasts are thought to have evolved from an ancestral endosymbiotic photosynthetic bacterium (see Figure 12-7). However, the endosymbiotic event that gave rise to chloroplasts occurred more recently (1.2 billion–1.5 billion years ago) than the event that led to the evolution of mitochondria (1.5 billion–2.2 billion years ago) (see Figure 1-1). Consequently, contemporary chloroplast DNAs show less sequence diversity than do mtDNAs. As with mtDNA, chloroplast DNA is inherited through the female parent (egg).

In higher plants, chloroplast DNA molecules are 120–160 kb long, depending on the species. Plant chloroplast DNAs are long head-to-

tail linear concatemers plus recombination intermediates between these long linear molecules. They contain 120–135 genes, 130 in the important model plant *Arabidopsis thaliana* (see Figure 1-23). *A. thaliana* chloroplast DNA encodes 76 protein-coding genes and 54 genes with RNA products such as rRNAs and tRNAs. Chloroplast DNAs encode the subunits of a bacteria-like RNA polymerase, and they express many of their genes from polycistronic operons, in which multiple proteins are translated from a single messenger RNA, as in bacteria. Some chloroplast genes contain introns, but these introns are similar to the specialized introns found in some bacterial genes and in mitochondrial genes from fungi and protozoans, rather than the introns of nuclear genes. Many genes essential for chloroplast function have been transferred to the nuclear genome of plants over evolutionary time. Chloroplast proteins that are encoded by nuclear genes are synthesized on cytosolic ribosomes and then incorporated into the organelle (see Chapter 13). Recent estimates from sequence analysis of the *A. thaliana* and cyanobacterial genomes indicate that somewhat less than 4500 genes have been transferred from the original endosymbiont to the nuclear genome.

Chloroplast DNA can be genetically manipulated by a process similar to that used for the transformation of yeast cells (see Chapter 6) or by techniques such as CRISPR/Cas9 to engineer plants that are resistant to bacterial and fungal infections, drought, and herbicides as well as engineered so that they can be used to make

human pharmaceutical drugs (called *pharming*). The first such pharming drug, approved in the United States for use in adults in 2012 and children in 2014, is an enzyme to treat Gaucher's disease, a genetic disorder. This approach might also be used for the engineering of food crops containing high levels of all the amino acids essential to humans. ■

Light Absorption by Photosystems in Chloroplasts Provides the Energy That Drives the Synthesis of NADPH and ATP and the Generation of O_2 from H_2O

In the 1950s, biophysicist Robert Emerson and colleagues discovered that the rate of plant photosynthesis generated by light of wavelength 700 nm could be greatly enhanced by adding light of shorter wavelengths (higher energy). They found that a combination of light at, say, 600 and 700 nm supports a rate of photosynthesis higher than the sum of the rates for the two separate wavelengths. This so-called Emerson effect led researchers to conclude that photosynthesis in plants, as well as in eukaryotic single-celled algae and in several photosynthetic bacteria (e.g., the cyanobacteria and prochlorophytes), involves the interaction of two separate multiprotein complexes called **photosystems**, each of which

absorbs light at defined wavelengths. Photosystems are found in all photosynthetic organisms, both eukaryotic and prokaryotic. We will focus on the two photosystems found in plants, **photosystem I (PSI)** that is primarily in unstacked regions of the thylakoid membranes and **photosystem II (PSII)** that is primarily in regions of stacked thylakoids (grana, see Figure 12-33).

Figure 12-34 shows an overview of the four stages of photosynthesis in plants. PSI (Figure 12-34, stage 2) is driven by light of 700 nm or less; PSII (Figure 12-34, stage 1), only by shorter wavelength light ($< 680\,\mathrm{nm}$). In stage 1 in cyanobacteria, algae, and plants PSII absorbs light, generates high energy electrons, and transfers those electrons to a quinone electron carrier, similar in structure to Coenzyme Q, called QH_2. PSII also forms O_2 from H_2O. In stage 2, the energy from the electrons in QH_2 drives a **proton pump** in the multiprotein cytochrome *bf* complex that generates a proton-motive force across the thylakoid membrane, which, as in mitochondria, is subsequently used for ATP production (stage 3). The energy-depleted electrons in the cytochrome *bf* complex are transferred by a small protein carrier called *plastocyanin* to PSI which uses light to reenergize the electrons that are then used by PSI to reduce $NADP^+$ to NADPH. The ATP and NADPH are used in stage 4 to incorporate carbon from CO_2 into small molecules (commonly referred to as **carbon fixation**) and then into six carbon sugars and starch.

FIGURE 12-34 Overview of the four stages of photosynthesis. In **stage 1**, light is absorbed by light-harvesting complexes (LHCs) and the reaction center of photosystem II (PSII). LHCs (yellow) transfer the absorbed energy to PSII's reaction center (black arrow), which use it or the energy absorbed directly from photons to (i) generate high-energy electrons (electron paths shown by blue arrows) and (ii) oxidize water to molecular oxygen via PSII's oxygen-evolving complex. In PSII, oxygen is formed on the lumenal side of the membrane, and the high-energy electrons are transferred to a quinone molecule, Q, bound near the stromal (cytosolic) face of the thylakoid membrane. The Q then combines with two protons to generate the lipid-soluble reduced quinone QH_2 that is released within the thylakoid membrane for diffusion to the cytochrome *bf* complex (Cyto *bf*) in **stage 2**. The oxygen-evolving complex of PSII contains a manganese (Mn, violet), calcium (green), and oxygen (red) cluster (Mn_4CaO_5, represented by the ball-and-stick model) that directly mediates the oxidation of water, as well as a bound Cl^- ion (teal) that influences the reaction rate.

In **stage 2**, QH_2 from **stage 1** binds to a site near the lumenal surface on the cytochrome *bf* complex (Cyto *bf*), a proton pump. The energy stored in QH_2 is released by a Q cycle similar

to that in mitochondrial complex III (see Figure 12-21). This energy drives protons from QH_2 and from the stroma across the thylakoid membrane to generate a proton-motive force. Then the two energy-depleted electrons originally from QH_2 are transferred from Cyto *bf*, via a water-soluble protein called *plastocyanin*, to photosystem I (PSI). After additional energy is transferred to those electrons by absorption of light in PSI and its associated LHC, they move to ferredoxin (FN) and then to ferredoxin-$NADP^+$ reductase (FNR), which uses their energy to reduce NAD and form the high-energy electron carrier NADPH. In **stage 3**, as in mitochondria, flow of protons down their concentration and voltage gradient through the F_0F_1 ATP synthase drives ATP synthesis. The chloroplast F_0F_1 ATP synthase generates one ATP for every 4–5 protons that pass through it. Stages 1–3 in plants take place in the thylakoid membrane of the chloroplast. In **stage 4**, in the chloroplast stroma, the energy stored in NADPH and ATP is used to incorporate CO_2 into the three-carbon molecule glyceraldehyde 3-phosphate, the first step in a process known as *carbon fixation*. These molecules are then transported to the cytosol of the cell for conversion to hexose sugars in the form of sucrose. Glyceraldehyde 3-phosphate is also used to make starch within the chloroplast. *Inset:* Three-dimensional reconstruction from cryoelectron tomography of a chloroplast in the unicellular green alga *Chlamydomonas reinhardtii*, showing thylakoid membranes (dark green), thylakoid lumen (light green), inner and outer membranes (blue), and one small starch granule (tan).

[Inset from Engel, B. D., et al., "Native Architecture of the Chlamydomonas Chloroplast Revealed by in Situ Cryo-Electron Tomography," *eLIFE*, 2015;4: e04889]

The overall reaction of oxygen-generating photosynthesis in plants,

$$6\,CO_2 + 6\,H_2O \rightarrow 6\,O_2 + C_6H_{12}O_6$$

is the reverse of the overall reaction by which carbohydrates are oxidized to CO_2 and H_2O. In effect, photosynthesis in chloroplasts produces energy-rich sugars that are broken down and harvested for energy by mitochondria using oxidative phosphorylation.

Photosynthesis in green and purple bacteria employs a PSI-like system, but not PSII, and does not generate oxygen.

In this section, we provide an overview of the stages in oxygen-generating photosynthesis and introduce the main molecular components of the process, including the chlorophylls, the principal light-absorbing pigments.

Three of the Four Stages in Photosynthesis Occur on the Thylakoid Membrane and Only During Illumination

Each of the four stages of photosynthesis is localized to a defined area of the chloroplast. All the reactions in stages 1–3 are catalyzed by multiprotein complexes embedded in the thylakoid membrane. The generation of a proton-motive force and the use of that proton-motive force to synthesize ATP resemble stages III and IV of mitochondrial oxidative phosphorylation. The enzymes of carbon fixation that incorporate CO_2 into chemical intermediates and then convert them to starch are soluble constituents of the chloroplast stroma; the enzymes that form sucrose from three-carbon intermediates are in the cytosol. All four stages of photosynthesis are tightly coupled and controlled so as to produce the amount of

carbohydrate required by the plant and to respond appropriately to environmental conditions.

The reactions that generate the ATP and NADPH used in carbon fixation are directly dependent on light energy; thus stages 1–3 are called the *light reactions* of photosynthesis. The reactions in stage 4 are indirectly dependent on light energy; they are sometimes called the *dark reactions* of photosynthesis because they can occur in the dark, using the supplies of ATP and NADPH generated by light energy (see Figure 12-34). However, the reactions in stage 4 are not confined to the dark; in fact, they occur primarily during illumination.

Stages 1 and 2 of Photosynthesis Convert Sunlight into High Energy Electrons That Generate a Proton-Motive Force and NADPH

The absorption of light energy and its conversion into chemical energy in plants occurs in photosystem II (PSII in stage 1 and photosystem I (PSI) in stage 2 (Figure 12-34). Photosystems — sometimes referred to as *core photosystems* — consist of two closely linked components: a *reaction center*, where the primary events of photosynthesis — light absorption and generation of high-energy

electrons — occur; and core *antenna complexes*. Each photosystem is also associated with external antenna complexes termed **light-harvesting complexes (LHCs)**, made up of specialized proteins that capture light energy and efficiently transmit it to the reaction center to generate high-energy electrons (see Figure 12-34).

The proteins of the reaction centers and the antenna complexes contain tightly bound light-absorbing pigment molecules. Chlorophyll *a*, the principal pigment involved in photosynthesis, is present in both reaction centers and antenna complexes. The initial step in photosynthesis is the absorption of light by chlorophyll *a* and other pigments. Like the heme component of cytochromes, chlorophylls consist of a porphyrin ring attached to a long hydrocarbon side chain (Figure 12-35). In contrast to the hemes (see Figure 12-17), chlorophylls contain a central Mg^{2+} ion (rather than Fe^{2+}) and have an additional five-member ring.

FIGURE 12-35 Structure of chlorophyll *a*, the principal pigment that traps light energy. Electrons are delocalized among three of chlorophyll *a*'s four central rings (yellow) and the atoms that interconnect them. In chlorophyll, a Mg^{2+} ion, rather than the Fe^{2+} ion found in heme, sits at the center of the porphyrin ring, and an additional five-member ring (blue) is present; otherwise, the structure of chlorophyll is similar to that of heme, found in molecules such as hemoglobin and cytochromes (see Figure 12-17a). The hydrocarbon phytol "tail" facilitates the binding of chlorophyll to hydrophobic regions of chlorophyll-binding proteins. The CH_3 group (green) is replaced by a formaldehyde (CHO) group in chlorophyll *b*.

The antenna complexes contain both chlorophyll *a* and other light-absorbing pigments, including other forms of chlorophyll (e.g., *chlorophyll* b in vascular plants) and *carotenoids* in both plants, algae, and photosynthetic bacteria. Carotenoids, of which there are several different molecular types, consist of long branched hydrocarbon chains with alternating single and double bonds; they are similar in structure to the visual pigment retinal (see Figure 15-34b), which absorbs light in the eye. The presence of various antenna pigments, which absorb light at different wavelengths, greatly extends the range of light that can be absorbed and used for photosynthesis. One of the strongest pieces of evidence for the involvement of chlorophylls and carotenoids in photosynthesis is that the absorption spectrum of these pigments is similar to the action spectrum of photosynthesis (Figure 12-36). The latter is a measure of the relative ability of light of different wavelengths to support photosynthesis.

EXPERIMENTAL FIGURE 12-36 The rate of photosynthesis is greatest at the wavelengths of light absorbed by three plant pigments. The action spectrum of photosynthesis in plants (the relative ability of light of different wavelengths to support photosynthesis) is shown in black. The energy from light can be converted into ATP only if it can be absorbed by pigments in the chloroplast. Absorption spectra (showing how well light of different wavelengths is absorbed) for three photosynthetic pigments (chlorophyll *a*, chlorophyll *b*, and β-carotene) present in the antennas of plant photosystems are shown in color. This figure shows as a function of the wavelength of light in nanometers (horizontal axis) a comparison of the action spectrum of photosynthesis (*right* vertical axis) with the individual absorption spectra of these pigments (*left* vertical axis). The data suggest that photosynthesis at 680 nm is primarily due to light absorbed by chlorophyll *a*; at 650 nm, to light absorbed by chlorophyll *b*; and at shorter wavelengths, to light absorbed by chlorophylls *a* and *b* and by carotenoid pigments, including β-carotene.

Quantum mechanics established that light, a form of electromagnetic radiation, has properties of both waves and particles. When light interacts with matter, it behaves as discrete packets of energy (quanta) called *photons*. The energy of a photon is proportional to the frequency of the light wave and thus inversely proportional to its wavelength. Thus photons of *shorter* wavelengths have *higher* energies. The energy of visible light is considerable. Light with a wavelength of $550\,\mathrm{nm}$ $(550 \times 10^{-7}\,\mathrm{cm})$, typical of sunlight, has about 52 kcal of energy per mole of photons. This is enough energy to synthesize several moles of ATP from ADP and P_i if all the energy were used for this purpose. However, in general in the electron-transport chain shown in stages 1–3 in Figure 12-34, the energy carried in 14 electrons derived from absorption of 28 photons (14 via photosystem II and 14 via photosystem I) is used to generate about 9 molecules of ATP and convert about 7 molecules of $NADP^+$ to NADPH.

When chlorophyll *a* (or any other molecule) absorbs visible light, the absorbed light energy raises electrons in the chlorophyll *a* to a higher energy (excited) state. This state differs from the ground (unexcited) state largely in the distribution of the electrons around the C and N atoms of the porphyrin ring. Excited states are unstable, and the electrons return to the ground state by one of several competing processes. For chlorophyll *a* molecules dissolved in organic solvents such as ethanol, the principal processes that dissipate the excited-state energy are: (1) the emission of light

(fluorescence and phosphorescence), (2) a process called *intersystem crossing* that leads to the transfer of energy to reactive oxygen species, and (3) thermal emission (heat). However, when the same chlorophyll *a* is bound in the unique protein environment of the reaction center, dissipation of excited-state energy occurs by a different process: the release of a high energy electron. As detailed in the next section, this is the key to photosynthesis.

Core Antenna Complexes and Light-Harvesting Complexes Increase the Efficiency of Photosynthesis

Two chlorophyll *a* molecules of the six chlorophylls within the reaction center are capable of directly absorbing light and initiating photosynthesis by a mechanism we will discuss shortly. In photosynthetic bacteria, the two bacteriochlorophylls that initiate photosynthesis are called the *special-pair bacteriochlorophylls*. Plants also have **special-pair chlorophylls** whose relative positions in the reaction center are similar to those in bacteria. Although in plants the specific pair of reaction-center chlorophylls responsible for initiating photosynthesis is not clear, for simplicity we will refer to the initiating chlorophylls in both plants and bacteria as the special-pair chlorophylls.

While the special-pair chlorophylls can directly absorb light to initiate photosynthesis, they are most commonly energized indirectly by energy transferred to them from other light-absorbing and energy-transferring pigments. These other pigments, which include many other chlorophylls, absorb photons and pass the energy to the special-pair chlorophylls (Figure 12-37). Some of these pigments are bound to protein subunits that are considered to be intrinsic components of the core photosystem, which is made up of several distinct protein chains. These pigment-containing proteins are called *core antenna complexes*. Other pigments are incorporated into protein complexes that bind to, but are distinct from, the core photosystems and are called *light-harvesting complexes (LHCs)*. The topological relationships of the reaction centers, core antennas and LHCs in the dimeric PSII-LHC supercomplex from the garden pea are illustrated in Figure 12-27d and e. Even at the maximum light intensity encountered by photosynthetic organisms (tropical noontime sunlight), each reaction-center chlorophyll *a* molecule directly absorbs only about one photon per second, which is not enough to support photosynthesis sufficient for the needs of the plant. The involvement of core antenna complexes and LHCs greatly increases the efficiency of photosynthesis, especially at more typical light intensities, by increasing absorption of 680-nm light and by extending the range of wavelengths of light that can be absorbed using other antenna pigments. For example, there are approximately 150 antenna chlorophyll molecules for each reaction center in plant PSII.

FIGURE 12-37 Light-harvesting complexes and photosystems in cyanobacteria and plants. (a) Diagram of the membrane of a cyanobacterium, in which each multiprotein light-harvesting complex (LHC, light yellow) contains 90 chlorophyll molecules (gray) and 31 other small molecules, all held in a specific geometric arrangement for optimal light absorption and energy transfer. Of the six chlorophyll molecules in the reaction center (dark and light green), two constitute the special-pair chlorophylls that initiate photoelectron transport (light blue arrow) when excited. The portions of the two reaction center quinone molecules are orange. Resonance energy transfer (pink arrows) rapidly funnels energy from absorbed light (wavy red arrows) to one of two "bridging" chlorophylls (blue) and thence to the special-pair chlorophylls (dark green) in the reaction center. (b) Three-dimensional organization of photosystem I (PSI) and its associated LHCs from *Pisum sativum* (garden pea), as determined by x-ray crystallography, seen from the plane of the membrane. Only the LHC chlorophylls (white with gray outlines) and the reaction-center electron carriers (same colors as in panel a) are shown. For simplicity, the special-pair chlorophylls are shown to initiate photoelectron transport (light blue arrow), although in plants the specific pair of

chlorophylls responsible is not clear. (c) Expanded view of the reaction center from (b), rotated 90° about a vertical axis. (d and e) Three-dimensional organization of the dimeric supercomplex of photosystem II (PSII) and its associated LHCs from *Pisum sativum* (garden pea), as determined by cryo-electron microscopy, seen from the plane of the membrane (panel d) or rotated 90° and viewed from the stroma (panel e). The 28 polypeptide chains in each monomeric supercomplex are colored based on their functions and locations: reaction center proteins D1 and D2 (pale green), internal antenna complexes - Core ant 47 and Core ant 43 - (lime green), and various LHC antenna proteins (light yellow). In addition to the reaction center and internal antennas, the PSII core contains 12 small proteins (dark green) and the oxygen-evolving complex on the luminal surface (shades of green, panel d). The 157 chlorophylls, 2 pheophytins (chlorophylls without the central magnesium), 44 carotenoids and other attached small molecules are white and gray. Two of the six electron-transporting cholorphylls present in the reaction center of PSI (panel a) are replaced in PSII by two pheophytins (not shown). The dimeric supercomplex comprises almost 100,000 atoms of which 73 percent compose the proteins. In panel e, the upper and lower monomers in the dimeric supercomplexe are separated by a black dotted line. The core PSII complex (reaction center, internal antennas and small associated proteins) is outlined in the upper monomer by a curved dashed line. In the lower monomer individual proteins are labeled: Reaction center D1/D2; core antenna complexes Core ant47 and Core ant43; and external antenna complexes, including the trimeric LHCII complexes t-LHCII-m and tLHCII-s and the monomeric antenna complexes mLHC-24, mLHC-26 and mLHC-29. See W. Kühlbrandt, 2001, *Nature* **411**:896, and P. Jordan et al., 2001, *Nature* **411**:909.

Photosystem core proteins and LHC proteins orient the pigment molecules in the precise orientations and positions that are optimal for light absorption and rapid (~ 0.2–200×10^{-12} seconds) energy transfer, called *resonance energy transfer*, to one of the special-pair chlorophyll *a* molecules in the associated reaction center. Resonance energy transfer does not involve the transfer of an

electron. Studies on one of the two photosystems in cyanobacteria, which are similar to those in multicellular, seed-bearing plants, suggest that energy from absorbed light is funneled first to a "bridging" chlorophyll in each LHC and then to the special-pair chlorophylls in the reaction center (see Figure 12-37a). Strikingly, the molecular structures of LHCs from plants and cyanobacteria are completely different from those from green and purple bacteria, even though both types contain carotenoids and chlorophylls. Figure 12-37b shows the distribution of the chlorophyll pigments in photosystem I from *Pisum sativum* (garden pea) together with those from peripheral LHC antennas. The large number of core and LHC antenna chlorophylls that surround the reaction center permit efficient transfer of absorbed light energy to the special-pair chlorophylls in the reaction center. Each chloroplast reaction center is associated with multiple internal antennas and light-harvesting complexes; the LHCs associated with PSII (e.g., LHCII) and with PSI (e.g., LHCI) contain different proteins. Cryoelectron microscopy has been used to determine the structure of a dimeric supercomplex of photosystem II and LHCII from the garden pea (Figure 12-37d and e). The structure reveals the relative positions of the proteins in its reaction center (pale green), internal antenna complexes (lime green), LHC antennas (light yellow) and other PSII core proteins (dark green), viewed both in the plane of the membrane (panel d) and from the stroma (panel e). Depending on light conditions, LHCIIs can dissociate from PSII and bind to PSI. Although LHC antenna chlorophylls can transfer light energy absorbed from a

photon, they cannot release an electron. As we've seen already, this function resides in the reaction-center chlorophylls.

Multiple Mechanisms Protect Cells Against Damage from Reactive Oxygen Species During Photoelectron Transport

As we saw earlier in the case of mitochondria, reactive oxygen species (ROS) generated during electron transport (see Figure 12-24) can both serve as signals to regulate organelle function and cause damage to a variety of biomolecules. The same is true of chloroplasts. For example, hydrogen peroxide (H_2O_2) regulates gas-exchange pores (stomata) in plants subjected to drought stress to prevent dehydration and controls cyclic electron flow.

Even though the PSI and PSII photosystems, with their associated light-harvesting complexes, are remarkably efficient at converting radiant energy to useful chemical energy in the form of ATP and NADPH — especially under low intensity light conditions — they are not perfect. Depending on the intensity of the light and the physiological conditions of the cells, a relatively small — but significant — amount of the energy absorbed by chlorophyll in the light-harvesting antennas and reaction centers results in the chlorophyll being converted to an activated state called *triplet*

chlorophyll. In this state, the chlorophyll can transfer some of its energy to molecular oxygen (O_2), converting it from its normal, *relatively* unreactive ground state, called *triplet oxygen* ($^3O_2$), to a very highly reactive (ROS) singlet state, $^1O_2$. Some of this $^1O_2$ can be used for signaling to the nucleus to communicate the metabolic state of the chloroplast to the rest of the cell. However if the majority of the $^1O_2$ is not quickly quenched (inactivated), it will react with, and usually damage, nearby molecules. This damage, called *photoinhibition*, can suppress the efficiency of thylakoid activity.

Chloroplasts use two major strategies for what is called *non-photochemical quenching* to avoid excess-light-induced damage. The first strategy for non-photochemical quenching is the use of specialized small organic *scavenger molecules* that quench the $^1O_2$ and are incorporated within photosystem/LHC supercomplexes. Examples include carotenoids (polymers of unsaturated isoprene groups, including β-carotene, which gives carrots their orange color) and α-tocopherol (a form of vitamin E). The second strategy involves dissipating the initially absorbed light energy as heat before it can generate damaging $^1O_2$. The extent of energy dissipation is regulated, depending on the light conditions. When exposed to intense light and thus the greatest risk of $^1O_2$-induced damage, the non-photochemical quenching is rapidly induced, and when light intensity falls, quenching is suppressed. The mechanisms underlying the second strategy include enzymatic changes in the structures of certain carotenoids and rapid responses to PSII-

dependent increases in the proton concentration in the thylakoid lumen.

KEY CONCEPTS OF SECTION 12.8

Chloroplasts and Photosynthesis

- Chloroplasts capture the energy of sunlight, convert it into chemical energy in the form of ATP and NADPH, and then use this energy to make complex carbohydrates out of carbon dioxide and water.
- The principal end products of photosynthesis in plants are molecular oxygen and polymers of six-carbon sugars (starch and sucrose).
- In chloroplasts, the light-capturing and ATP- and NADPH- generating reactions of photosynthesis occur in the thylakoid membrane. The permeable outer membrane and the inner membrane surrounding the thylakoid membrane in chloroplasts do not participate directly in photosynthesis (see Figures 12-33 and 12-34).
- Like mitochondria, chloroplasts contain their own DNA and are thought to have evolved from an ancestral endosymbiotic photosynthetic bacterium.
- Plants contain two light-absorbing photosystems, PSI and PSII, which have different functions and are physically separated in the thylakoid membrane. PSII generates high-energy electrons that convert the quinone Q to QH_2 and convert H_2O into O_2, and PSI reduces $NADP^+$ to NADPH. Cyanobacteria have two analogous photosystems.
- There are four stages in photosynthesis: (1) absorption of light, generation of high-energy electrons, and formation of O_2 from H_2O; (2) electron transport leading to generation of a proton-motive force, absorption of light to reenergize electrons, and reduction of $NADP^+$ to NADPH; (3) synthesis of ATP; and (4) conversion of CO_2 into carbohydrates (carbon fixation). The overall reaction of oxygen-generating photosynthesis in plants is $6\,CO_2 + 6\,H_2O \rightarrow 6\,O_2 + C_6H_{12}O_6$ (see Figure 12-34).
- In photosystems (PSI and PSII), light energy is transferred directly or indirectly to one of two special-pair chlorophyll *a* molecules bound to reaction-center proteins in the thylakoid membrane. This energy is used to generate a high-energy electron that separates from a positively charged chlorophyll *a* by a process called *photoelectron transport*. The high-energy electrons drive the generation of NADPH and ATP.
- In photosystems, the reaction centers are bound to multiple internal antennas and external antennas that contain chlorophylls *a* and *b*, carotenoids, and other pigments that absorb light at multiple wavelengths. The external antennas are called *light-*

harvesting complexes (LHCs). Depending on light conditions, LHCIIs can dissociate from PSII to which they often bind and bind to PSI. Energy, but not electrons, is transferred from the pigments in the internal antennas and the LHCs to the special-pair chlorophylls in the reaction center by resonance energy transfer to increase the capacity to convert light to high-energy electrons for photosynthesis (see Figure 12-37).

- The absorption of light by pigments in the chloroplast can generate reactive oxygen species (ROS), including singlet oxygen, $^1O_2$, and hydrogen peroxide, H_2O_2. In small amounts, they are used as intracellular signaling molecules; in larger amounts, they can be toxic.
- Chloroplasts employ multiple strategies for preventing the buildup of damaging $^1O_2$. For example, small-molecule scavengers, such as carotenoids, and antioxidant enzymes help to protect against ROS-induced damage. Chloroplasts also use regulated non-photochemical quenching mechanisms to protect against light-induced damage.

12.9 Use of Light Energy to Generate Molecular Oxygen, NADPH, and ATP in Stages 1–3 of Photosynthesis

In the previous section, we presented an overview of the four stages of photosynthesis. In this section, we will describe some of the molecular details of how in stages 1 and 2 light energy is used to generate O_2 from H_2O, generate NADPH from $NADP^+$, and produce a proton-motive force, and how in stage 3 that proton-motive force drives the synthesis of ATP from ADP and P_i (see Figure 12-34).

The First Three Stages of Photosynthesis

Stage 1: Absorption of Light Energy by PSII, Generation of High-Energy Electrons, and Formation of O_2 from Water

Within the reaction center of PSII, two adjacent special-pair chlorophylls lie close to the luminal face of the thylakoid membrane (Figure 12-38). When a photon of light with a wavelength of about 680 nm is absorbed by one of these two chlorophyll *a* molecules in

purple bacteria, the energy of that chlorophyll *a* molecule increases by 42 kcal/mol (the first excited state). This energized molecule rapidly donates an electron to the adjacent chlorophyll, which passes it on to a series of intermediate small-molecule acceptors bound to the PSII. These transfers are represented by the zigzag blue lines in Figure 12-34 and in Figure 12-38 (*left*). The electron is rapidly passed on to the primary electron acceptor, which is the oxidized form of a molecule called *quinone (Q)*, near the stromal surface of the thylakoid membrane (Figures 12-34 and 12-38). Q is similar in structure and function to CoQ in mitochondria, in that it is a small, lipid-soluble, organic molecule that serves as an electron carrier that undergoes oxidation to Q and reduction to QH_2. This light-driven electron transfer, called **photoelectron transport**, is very efficient and depends on the environment of both the chlorophylls and the acceptor within the reaction center. Photoelectron transport, which occurs nearly every time a photon is absorbed, leaves a positive charge on the chlorophyll *a* (chlorophyll a^+) close to the luminal surface of the thylakoid membrane (on the opposite side from the stroma) and generates a high-energy electron that moves to Q to form the negatively charged acceptor (Q^-) near the stromal surface.

FIGURE 12-38 Photoelectron transport in a photosystem, the primary event in photosynthesis. After absorption of a photon of light, one of the excited special-pair chlorophyll *a* molecules in the reaction center (*left*) donates, via several intermediates (not shown), an electron to a loosely bound acceptor molecule, the quinone Q, on the stromal surface of the thylakoid membrane, creating an essentially irreversible charge separation across the membrane (*right*). Subsequent transfers of this electron release energy that is used to generate a proton gradient and thus ATP and NADPH (see Figures 12-34). The positively charged chlorophyll a^+ generated when the light-excited electron moves to Q is eventually neutralized by the transfer to the chlorophyll a^+ of another electron. In plants, the oxidation of H_2O to O_2 provides this neutralizing electron and takes place in PSII (see Figure 12-34). Photosystem I uses a similar photoelectron-transport pathway, but as we will see below, instead of oxidizing water, it receives an electron from a protein carrier called *plastocyanin* to neutralize the positive charge on chlorophyll a^+ (see Figure 12-34).

Absorption of a second photon and transfer of a second electron to Q^- forms a powerful reducing agent that combines with two protons

to form QH_2, the reduced form of the quinone. QH_2 is a source of high-energy electrons and protons for stage 2 described below. The herbicide *atrazine* is one of the most commonly used weed killers in US agriculture. Atrazine binds to PSII, blocks the binding of Q, and thus blocks formation of QH_2 and downstream electron transport.

The positively charged special-pair reaction-center chlorophyll a^+ is the *strongest* biological oxidant known. In plants, the oxidizing power of four chlorophyll a^+ molecules is used by a subcomplex in PSII called the *oxygen-evolving complex* (Mn_4CaO_5, see Figure 12-34) to remove four electrons from two H_2O molecules bound to a site on the luminal surface to form O_2:

$$2\,H_2O + 4\,\text{chlorophyll}\,a^+ \rightarrow 4\,H^+ + O_2 + 4\,\text{chlorophyll}\,a$$

However, absorption of each photon by PSII results in the transfer of just one electron. Thus it is necessary for a single PSII to lose an electron and then partially oxidize the oxygen-evolving complex, and then sequentially repeat this process three more times in order for its oxygen-evolving complex to extract four electrons from two water molecules and generate one O_2 molecule. These potent biological reductants and oxidants along with PSI provide all the energy needed to drive all subsequent reactions of photosynthesis: electron and proton transport and NADPH synthesis (stage 2), ATP synthesis (stage 3), and CO_2 fixation (stage 4).

Chlorophyll *a* can absorb light at discrete wavelengths shorter (and therefore of higher energy) than 680 nm (see Figure 12-36). Such absorption raises the molecule into one of several excited states whose energies are higher than that of the first excited state described above. These higher excited states decay to the lower energy first excited state by releasing energy in $\sim$100–200 $\times$ 10^{-15} seconds (~100–200 femtoseconds, fs) as heat. Because photoelectron transport and the resulting charge separation occur only from the first excited state of the reaction-center chlorophyll *a*, the quantum yield — the amount of photosynthesis per absorbed photon — is the same for all wavelengths of visible light shorter than 680 nm. How closely the wavelength of light matches the absorption spectrum of the pigment determines how likely it is that the photon will be absorbed. Once absorbed, the photon's exact wavelength is not critical, provided it is at least energetic enough (has a short enough wavelength) to push the chlorophyll *a* into the first excited state.

In chloroplasts, the special-pair reaction-center chlorophylls that initiate photoelectron transport in PSII and in PSI differ in their light-absorption maxima (680 and 700 nm, respectively) because of differences in their protein environments. For this reason, these chlorophylls are often denoted P_{680} (PSII) and P_{700} (PSI). Furthermore, the two photosystems are distributed differently in thylakoid membranes: PSII primarily in regions of stacked thylakoids (grana, see Figure 12-33) and PSI primarily in unstacked

regions. The stacking of thylakoid membranes may be due to the binding properties of the proteins associated with PSII, especially light-harvesting complexes.

Stage 2: Generation of a Proton-Motive Force and NADPH

Electrons move from the quinone primary electron acceptor QH_2 generated in stage 1 to a proton pump, called the *cytochrome* bf *complex*, in stage 2 (Figure 12-34). The high energy electrons in QH_2 provide the energy for the cytochrome *bf* complex to drive across the thylakoid membrane protons from QH_2 as well as protons from the stroma to generate a proton-motive force, forming a pH gradient across the membrane ($pH_{lumen} < pH_{stroma}$). This process is analogous to the generation of a proton-motive force across the inner mitochondrial membrane and in bacterial membranes during electron transport (see Figure 12-25). A small, water-soluble, copper-containing, electron carrier protein called *plastocyanin* transfers the now lower energy electrons from the cytochrome *bf* complex to a complex called *photosystem I (PSI)* (see Figure 12-34). The electrons from QH_2 lose considerable energy by driving proton pumping and thus have relatively low energy when they are transferred to PSI from plastocyanin. After additional energy is transferred to those electrons by absorption of light in photosystem I (PSI) by special-pair chlorophylls, they move to two protein components of PSI, first to ferredoxin (FN) and then to ferredoxin-$NADP^+$ reductase (FNR),

which use the energy in these electrons to drive the synthesis of the high-energy electron carrier NADPH from its oxidized form, **nicotinamide adenine dinucleotide phosphate ($NADP^+$)**. The structure of $NADP^+$ is identical to that of NAD^+ except for the presence of an additional phosphate group. Both molecules gain and lose electrons in the same way (see Figure 2-33).

Thus the overall reaction of stages 1 and 2 can be summarized as

$$2H_2O + 2NADP^+ \xrightarrow{\text{Light}} 2H^+ + 2NADPH + O_2$$

Generation of a Proton-Motive Force, but No NADPH or O_2, in Stage 2 by Cyclic Electron Flow

Stage 2 generates a proton gradient (used to make ATP in stage 3) and NADPH, and the pathway of stage 2 shown in Figure 12-34 has been called the *linear electron flow* pathway. In some circumstances, however, especially when plants are stressed by conditions such as drought, high light intensity, or low carbon dioxide levels, cells must generate greater amounts of ATP relative to NADPH than they can produce by linear electron flow. To do this, they photosynthetically produce ATP from PSI without concomitant NADPH production. This is accomplished by a PSI-dependent and PSII-independent process called *cyclic photophosphorylation*, or *cyclic electron flow* (Figure 12-39). In this process, electrons cycle among PSI, ferredoxin, plastoquinone (Q), and the cytochrome *bf* complex,

bypassing the ferredoxin-$NADP^+$ reductase at PSI that normally generates NADPH. Thus during cyclic electron flow, proton pumping permits additional ATP synthesis, but no *net* NADPH is generated, and there is no oxidization of H_2O to produce O_2.

FIGURE 12-39 Cyclic electron flow in plants, which generates a proton-motive force and ATP but no oxygen or NADPH. In cyclic electron flow, light energy is used by PSI to transport electrons in a cycle to generate a proton-motive force and subsequently in stage 3 ATP, without oxidizing water or generating NADPH. High-energy electrons are transferred via the ferredoxin of PSI either to a PGR5-PGRL1 heterodimer (red, *left* pathway) or to the NADH dehydrogenase–like complex (blue, *right* pathway), where they then reduce plastoquinone (Q) to QH_2. Each of these two electron acceptors forms independent supercomplexes with PSI via light-harvesting complex (LHC) subunits (yellow). (The PGR5-PGRL1 heterodimer and NADH dehydrogenase–like complex are not found together in the same supercomplex, but here are drawn together with only one PSI to emphasize the similarities of the two mechanisms of cyclic electron flow.) QH_2 then transfers the electrons to the cytochrome *bf* complex, then to plastocyanin, and finally back to PSI, as is the case for the linear electron flow pathway (see Figure 12-34).

In higher plants, there are two cyclic electron flow pathways that control the ATP:NADPH ratio (see Figure 12-39). The major pathway is the PGR5-PGRL1-dependent pathway, which we shall describe shortly; this pathway ensures efficient photosynthesis and protects against stress. The minor pathway is the *NADH dehydrogenase–like complex-dependent pathway*, which appears to respond to stress and to be a target of H_2O_2-mediated regulation. The NADH dehydrogenase–like complex is a very large multiprotein complex that is very similar in shape and composition to mitochondrial complex I (see Figure 12-19), which oxidizes NADPH or NADH while reducing CoQ to $CoQH_2$. The NADH dehydrogenase–like complex, however, appears to lack the subunit necessary for NADPH oxidation.

During cyclic electron flow, high-energy electrons generated by light absorption and photoelectron transport in PSI are transferred either to the PGR5-PGRL1 heterodimer or to the NADH dehydrogenase–like complex from the ferredoxin subunit of PSI. Indeed, there is evidence that each of these two electron acceptors independently associates with PSI in supercomplexes mediated by LHC subunits. Both of these electron acceptors then reduce Q to QH_2, which then delivers protons and electrons to the cytochrome *bf* complex via a Q cycle, as we described earlier for linear electron flow (see Figure 12-34). Protons are transported across the thylakoid membrane into the lumen by the cytochrome *bf* complex and possibly by the NADH dehydrogenase–like complex. Finally, plastocyanin returns the

electrons from the cytochrome *bf* complex to PSI to complete the cycle. The proton-motive force generated by cyclic electron flow drives ATP synthesis by the F_0F_1 complex (ATP synthase) and thus increases the ATP:NADPH ratio.

Stage 3: Synthesis of ATP

The light-driven proton gradient generated across the thylakoid membrane in stages 1 and 2 can then be used to drive ATP synthesis (see Figure 12-34). The protons move down their concentration gradient from the thylakoid lumen to the stroma through the chloroplast F_0F_1 complex (ATP synthase), which couples proton movement to the synthesis of ATP from ADP and P_i, as we have seen for the ATP synthases in mitochondria and bacteria (see Figures 12-27, 12-28, and 12-33).

Relative Activities of Photosystems I and II Are Regulated

Chloroplasts respond to changes in the wavelengths and intensities of ambient light (as a consequence of the time of day, cloudiness, etc.) by altering the relative outputs of PSI and PSII to maintain the appropriate balance of ATP and NADPH production.

One mechanism underlying the regulation of the relative activities of PSI (preferentially located in the unstacked thylakoid membranes) and PSII (preferentially located in the stacked grana) is phosphorylation and dephosphorylation of thylakoid membrane proteins, including PSII and LHCII. Changes in phosphorylation, particularly for LHCII, can alter the intra–thylakoid membrane distribution (grana vs. unstacked membranes) of this antenna complex and thus its differential interactions with PSI and PSII. The more LHCII is associated with a particular photosystem, the more efficiently that system will be activated by light, and the greater its contribution to electron flow. It appears that the efficient operation of electron-transport chains has involved the evolution of functional complexes of increasing size and complexity, from individual proteins to complexes to supercomplexes to super-supercomplexes. Regulating the supramolecular organization of the photosystems in plants has the effect of directing them toward primarily ATP production alone or toward the generation of reducing equivalents (NADPH) and ATP, depending on ambient light conditions and the metabolic needs of the plant. Both NADPH and ATP are required to convert CO_2 to sucrose or starch, the fourth stage in photosynthesis, which we cover in the next section.

KEY CONCEPTS OF SECTION 12.9

Use of Light Energy to Generate Molecular Oxygen, NADPH, and ATP in Stages 1–3 of Photosynthesis

- In stage 1 of photosynthesis (see Figure 12-34), light energy is converted by photosystem II (PSII) into high energy electrons that are transferred by photoelectron transport from the special-pair chlorophylls, via intermediates, to a quinone (Q) on the opposite side of the membrane, generating a charge separation (see Figure 12-38) and the small lipid-soluble electron transport molecule QH_2.
- In green plants, the positively charged chlorophyll created by photoelectron transport in PSII is regenerated to the neutral, reduced form by the oxygen-evolving complex subunit of PSII. Electrons from water are transferred by the oxygen-evolving complex to the positively charged chlorophyll of PSII, resulting in the formation of molecular oxygen (O_2) in the thylakoid lumen.
- In stage 2 (see Figure 12-34), high-energy electrons are transported from the reduced quinone QH_2 from stage 1 to a proton pump (cytochrome *bf* complex) that moves across the membrane protons from both QH_2 and the stroma to the thylakoid lumen, forming a pH gradient (proton-motive force) across the thylakoid membrane.
- The electrons depleted of energy by the cytochrome *bf* complex during proton pumping are transferred by the water-soluble protein plastocyanin to PSI, where they reenergize when light energy is absorbed by its special-pair chlorophylls.
- Photoelectron transport within PSI transfers the reenergized electrons to the ultimate electron acceptor, usually $NADP^+$, reducing it to NADPH.
- The relative activities of PSI and PSII are regulated to maintain the appropriate balance of ATP and NADPH production.
- Reversible phosphorylation and dephosphorylation of the light-harvesting complex II (LHCII) control the functional organization of the photosynthetic apparatus in thylakoid membranes to regulate the relative activities of PSI and PSII and thus the relative amounts of ATP and NADPH generated. Very large super-supercomplexes appear to be involved in this regulation.
- In stage 3, movement of protons down their electrochemical gradient generated in stage 2 (proton-motive force) through F_0F_1 complexes (ATP synthase) powers the synthesis of ATP from ADP and P_i.

12.10 ATP and NADPH Drive Carbon Fixation in the Calvin Cycle and Carbohydrate Synthesis in Stage 4 of Photosynthesis

In stage 4, the NADPH and ATP generated in stages 2 and 3 drive the synthesis from CO_2 and H_2O of six-carbon sugars (and their polymers). The overall chemical equation is

$$\begin{aligned} &6\,CO_2 + 18\,ATP^{4-} + 12\,NADPH + 12\,H_2O \rightarrow \\ &\qquad C_6H_{12}O_6 + 18\,ADP^{3-} + 18\,P_i^{2-} + 12\,NADP^+ + 6\,H^+ \end{aligned}$$

In addition to CO_2 fixation — incorporation of gaseous CO_2 into small organic molecules and then sugars — the synthesis of almost all amino acids, all fatty acids and carotenes, all pyrimidines, and probably all purines occurs in chloroplasts. The synthesis of sugars from CO_2 is the most extensively studied biosynthetic pathway in plant cells. We first consider the unique pathway, known as the **Calvin cycle** (after discoverer Melvin Calvin), that fixes CO_2 into three-carbon compounds, powered by energy released during ATP hydrolysis and oxidation of NADPH. Because CO_2 is initially incorporated into a three-carbon compound, the Calvin cycle is also called the C_3 *pathway* of carbon fixation.

Rubisco Fixes CO_2 in the Chloroplast Stroma

In the first step of the Calvin cycle (Figure 12-40, *top*), the enzyme **ribulose 1,5-bisphosphate carboxylase**, or **rubisco**, incorporates CO_2 into precursor molecules that are subsequently converted into carbohydrates. Rubisco is located in the stroma of the chloroplast. This enzyme adds CO_2 to the five-carbon sugar ribulose 1,5-bisphosphate to form two molecules of the three-carbon compound 3-phosphoglycerate (Figure 12-41). Rubisco is a large enzyme ($\sim 520\,\mathrm{kDa}$) whose most common form is composed of eight identical large and eight identical small subunits. The large subunit, which contains the catalytic site, is encoded in chloroplast DNA and the small subunit is encoded by a family of genes in the nucleus. Because the catalytic rate of rubisco is quite low, many copies of the enzyme are needed to fix sufficient CO_2. Indeed, this enzyme makes up almost 50 percent of the soluble protein in a chloroplast and is believed to be the most abundant protein on Earth. It is estimated that rubisco fixes more than 10^{11} tons of atmospheric CO_2 each year.

FIGURE 12-40 The pathway of carbon during photosynthesis. *Top*: Six molecules of CO_2 are converted into two molecules of glyceraldehyde 3-phosphate. These reactions, which constitute the Calvin cycle, occur in the stroma of the chloroplast. Via the phosphate/triosephosphate antiporter, some glyceraldehyde 3-phosphate is transported

to the cytosol in exchange for phosphate. No fixed CO_2 leaves the chloroplast unless phosphate is fed into it to replace the phosphate carried out of the stroma in the form of glyceraldehyde 3-phosphate. *Bottom*: In the cytosol, an exergonic series of reactions converts glyceraldehyde 3-phosphate to fructose 1,6-bisphosphate. Two molecules of fructose 1,6-bisphosphate are used to synthesize one molecule of the disaccharide sucrose and release inorganic phosphate that can be transported back into the stroma. The mechanism of the conversion of glyceraldehyde 3-phosphate to hexoses is almost the reverse of that in glycolysis (see Figure 12-3). Some glyceraldehyde 3-phosphate (not shown here) is also converted to amino acids and fats, compounds essential for plant growth.

FIGURE 12-41 The initial reaction of rubisco that fixes CO_2 into organic compounds. In this reaction, catalyzed by ribulose 1,5-bisphosphate carboxylase (rubisco), CO_2 (red) condenses with the five-carbon sugar ribulose 1,5-bisphosphate. The products are two molecules of 3-phosphoglycerate.

Rubisco is a light- and redox-sensitive enzyme, although its regulation is very complex and not yet fully understood. Rubisco is spontaneously activated in the presence of high CO_2 and Mg^{2+} concentrations. The activating reaction entails the covalent addition of CO_2 to the side-chain amino group of a lysine in the enzyme's active site, forming a carbamate group that then binds a Mg^{2+} ion, which is required for enzymatic activity. Under normal conditions,

however, with ambient levels of CO_2, this reaction is slow and usually requires catalysis by *rubisco activase*, a member of the AAA^+ family of ATPases. Rubisco activase hydrolyzes ATP and uses the energy released to clear the active site of rubisco of small molecule inhibitors so that CO_2 can be added to its active site lysine. Rubisco activase also accelerates an activating conformational change in rubisco (from an inactive-closed to an active-opened state). The regulation of rubisco activase by the protein *thioredoxin (Tx)* is, at least in part in some species, responsible for rubisco's light/redox sensitivity. In the dark, thioredoxin contains a disulfide bond; in the light, electrons are transferred from PSI, via ferredoxin, to thioredoxin, reducing its disulfide bond:

In the dark, when thioredoxin becomes reoxidized, rubisco activase and other enzymes are reoxidized and so inactivated. Thus the activities of these enzymes are sensitive to the redox state of the stroma, which in turn is light sensitive — an elegant mechanism for the regulation of enzymatic activity by light.

Furthermore, rubisco activase's activity is sensitive to the ratio of ATP to ADP. If that ratio is low (relatively high ADP), then the

activase will not activate rubisco (and so the cell will expend less of its scarce ATP to fix carbon). Photosynthesis is sensitive to a variety of typical plant stresses — moderate heat, cool temperatures, drought (limited water), high salt, high light intensity, and UV radiation. At least some of these stresses influence CO_2 fixation by reducing the activity of rubisco activase and thus rubisco. Inhibition of CO_2 fixation reduces consumption of NADPH. Under strong light conditions, the high $NADPH/NADP^+$ ratio can reduce electron flow to $NADP^+$ and increase leakage to O_2, resulting in increased ROS formation, which can both initiate cellular-signaling pathways and interfere with a variety of cellular processes. Given the key role of rubisco in controlling energy utilization and carbon flux — both in individual chloroplasts and, in a sense, throughout the entire biosphere — it is not surprising that its activity is carefully regulated.

The fate of 3-phosphoglycerate formed by rubisco is complex: some is converted to hexoses incorporated into starch or sucrose, but some is used to regenerate ribulose 1,5-bisphosphate. The fixation of 6 CO_2 molecules and the net formation of 2 glyceraldehyde 3-phosphate molecules (see Figure 12-40, *top*) require the consumption of 18 ATPs and 12 NADPHs generated by the light-requiring processes of photosynthesis.

Synthesis of Sucrose Using Fixed CO_2 Is Completed in the Cytosol

After its formation in the chloroplast stroma, glyceraldehyde 3-phosphate is transported to the cytosol in exchange for phosphate. The final steps of sucrose synthesis (Figure 12-40, *bottom*) occur in the cytosol of leaf cells.

Synthesis of Starch in the Stroma

The key monomer substrate used to build large starch polymers is ADP-glucose. This polymerization takes place in the stroma, and starch polymers are stored there in densely packed crystalline aggregates called *granules* (see Figures 12-33 and 12-34). The enzymes that generate ADP-glucose from glucose 1-phosphate and ATP are found in both the stroma and the cytosol, indicating that hexoses of various structures are imported from the cytosol into the stroma for starch synthesis.

Photorespiration Competes with Carbon Fixation and Is Reduced in C_4 Plants

As noted above, rubisco catalyzes the incorporation of CO_2 into ribulose 1,5-bisphosphate as part of photosynthesis. It can catalyze a second, distinct, and *competing* reaction with the same substrate — ribulose 1,5-bisphosphate — but with O_2 in place of CO_2 as a second substrate, in a process known as **photorespiration** (Figure 12-42).

The products of this second reaction are one molecule of 3-phosphoglycerate and one molecule of the two-carbon compound phosphoglycolate. The carbon-fixing reaction is favored when the ambient CO_2 concentration is relatively high, whereas photorespiration is favored when CO_2 is low and O_2 is relatively high. Photorespiration takes place in light, consumes O_2, and converts ribulose 1,5-bisphosphate in part to CO_2. As Figure 12-42 shows, photorespiration is wasteful to the energy economy of the plant: it consumes ATP and O_2, and it generates CO_2 without fixing carbon. Indeed, when CO_2 is low and O_2 is high, much of the CO_2 fixed by the Calvin cycle is lost as the result of photorespiration. This surprising, wasteful alternative reaction catalyzed by rubisco may be a consequence of the inherent difficulty the enzyme has in specifically binding the relatively featureless CO_2 molecule and of the ability of both CO_2 and O_2 to react and form distinct products with the same initial enzyme/ribulose 1,5-bisphosphate intermediate.

FIGURE 12-42 CO_2 fixation and photorespiration. These competing pathways are both initiated by ribulose 1,5-bisphosphate carboxylase (rubisco), and both use ribulose 1,5-bisphosphate. CO_2 fixation (pathway **1**) is favored by high CO_2 and low O_2 concentrations; photorespiration (pathway **2**) occurs at low CO_2 and high O_2 concentrations (i.e., under normal atmospheric conditions). The phosphoglycolate produced by photorespiration is recycled via a complex set of reactions that take place in peroxisomes and in mitochondria, as well as in chloroplasts. The net result: for every two molecules of phosphoglycolate formed by photorespiration (four C atoms), one molecule of 3-phosphoglycerate is ultimately formed and recycled, and one molecule of CO_2 is lost.

Excessive photorespiration could become a problem for plants in a hot, dry environment because they must keep the gas-exchange pores (stomata) in their leaves closed much of the time to prevent excessive loss of moisture. As a consequence, the CO_2 level inside the leaf can fall below the K_m of rubisco for CO_2. Under these conditions, the rate of photosynthesis is slowed, photorespiration is greatly favored, and the plant might be in danger of fixing inadequate amounts of CO_2. Corn, sugarcane, crabgrass, and other

plants that can grow in hot, dry environments have evolved a way to avoid this problem by using a two-step pathway of CO_2 fixation in which a CO_2-hoarding step in cells called *mesophyll cells* precedes the Calvin cycle in cells called *bundle sheath cells* (Figure 12-43). This pathway has been named the **C_4 pathway** because the first molecules formed in mesophyll cells during carbon fixation in this pathway are four-carbon compounds, such as oxaloacetate and malate, rather than the three-carbon molecules that initiate the Calvin cycle (C_3 pathway). These four-carbon molecules then move into bundle sheath cells where they release CO_2 that serves as a substrate for the Calvin cycle. The relatively high concentration of CO_2 and low concentration of O_2 in bundle sheath cells favor the fixation of CO_2 by rubisco to form 3-phosphoglycerate and suppress photorespiration.

FIGURE 12-43 The C_4 pathway. The key enzyme in the C_4 pathway is phosphoenolpyruvate carboxylase, which assimilates CO_2 (red) to form oxaloacetate in mesophyll cells.

Decarboxylation of malate or other C_4 intermediates in bundle sheath cells releases CO_2, which enters the standard Calvin cycle via rubisco (see Figure 12-40, *top* and 12-41).

C_4 plants are superior to C_3 plants in their ability to use the available CO_2 because the C_4 enzyme phosphoenolpyruvate carboxylase has a higher affinity for CO_2 than does rubisco. However, one ATP is converted to one AMP in the cyclical C_4 process (to generate phosphoenolpyruvate from pyruvate); thus the overall efficiency of the photosynthetic production of sugars from NADPH and ATP is lower than it is in C_3 plants, which use only the Calvin cycle for CO_2 fixation. Nonetheless, the net rates of photosynthesis for C_4 grasses, such as corn or sugarcane, can be two to three times the rates for otherwise similar C_3 grasses, such as wheat, rice, or oats, owing to the elimination of losses from photorespiration.

KEY CONCEPTS OF SECTION 12.10

ATP and NADPH Drive Carbon Fixation in the Calvin Cycle and Carbohydrate Synthesis in Stage 4 of Photosynthesis

- In stage 4, the NADPH and ATP generated in stages 2 and 3 provide the energy and the electrons to drive the fixation of CO_2, which results in the synthesis of carbohydrates. These reactions occur in the thylakoid stroma and cytosol.
- Stages 1–3 are called the *light reactions* of photosynthesis because they are directly dependent on light energy. The reactions in stage 4 are indirectly dependent on light energy; they are sometimes called the *dark reactions* of photosynthesis because they can occur in the dark, although they often occur during illumination.
- In the Calvin cycle, also called the C_3 *pathway* of carbon fixation, atmospheric CO_2 is incorporated, or fixed, into organic molecules in a series of reactions that occur in the chloroplast stroma.

- The initial reaction in the Calvin cycle, catalyzed by the enzyme rubisco, forms a three-carbon intermediate, 3-phosphoglycerate. Some of the glyceraldehyde 3-phosphate generated in the cycle is transported to the cytosol and converted to sucrose (see Figure 12-40).
- Rubisco is light- and redox-sensitive. Its activity is regulated by the enzyme rubisco activase.
- ADP-glucose is polymerized to starch polymers in the stroma, where they are stored in densely packed aggregates called *granules*.
- In C_3 plants, a substantial fraction of the CO_2 fixed by the Calvin cycle can be lost as the result of photorespiration, a wasteful reaction catalyzed by rubisco that is favored at low CO_2 and high O_2 levels (see Figure 12-42).
- In C_4 plants, CO_2 is fixed initially in the mesophyll cells by a rubisco-independent reaction with phosphoenolpyruvate. The four-carbon molecules so generated are shuttled to the bundle sheath cells, where the CO_2 is released and then fixed by rubisco in the Calvin cycle. The rate of photorespiration in C_4 plants is much lower than it is in C_3 plants.

Review the Concepts

1. The proton-motive force is essential for both mitochondrial and chloroplast function. What produces the proton-motive force, and what is its relationship to ATP? The compound 2,4-dinitrophenol (DNP), which was used in diet pills in the 1930s but later shown to have dangerous side effects, allows protons to diffuse across membranes. Why is it dangerous to consume DNP?
2. Mitochondria and chloroplasts are thought to have evolved from symbiotic bacteria. What is the experimental evidence from this chapter that supports this hypothesis?
3. The inner mitochondrial membrane exhibits all of the fundamental characteristics of a typical cell membrane, but it also has several unique characteristics that are closely associated with its role in oxidative phosphorylation. What are these unique characteristics? How does each contribute to the function of the inner membrane?
4. Maximal production of ATP from glucose involves the reactions of glycolysis, the citric acid cycle, and the

electron-transport chain. Which of these reactions requires O_2, and why? Which, in certain organisms or physiological conditions, can proceed in the absence of O_2?

5. Fermentation permits the continued extraction of energy from glucose in the absence of oxygen. If glucose catabolism is anaerobic, why is fermentation necessary for glycolysis to continue?
6. Describe the step-by-step process by which electrons from glucose catabolism in the cytoplasm are transferred to the electron-transport chain in the inner mitochondrial membrane. In your answer, note whether the electron transfer at each step is direct or indirect.
7. Mitochondrial oxidation of fatty acids is a major source of ATP, yet fatty acids can be oxidized elsewhere. What organelle, besides the mitochondrion, can oxidize fatty acids? What is the fundamental difference between oxidation occurring in this organelle and mitochondrial oxidation?
8. Each of the cytochromes in the mitochondrion contains prosthetic groups. What is a prosthetic group? Which type of prosthetic group is associated with the cytochromes? What property of the various cytochromes ensures unidirectional electron flow along the electron-transport chain?
9. The electron-transport chain consists of a number of multiprotein complexes, which work in conjunction to pass electrons from an electron carrier, such as NADH, to O_2. What is the role of these complexes in ATP synthesis? It has

been demonstrated that respiration supercomplexes contain all the protein components necessary for respiration. Why is this beneficial for ATP synthesis, and what is one way that the existence of supercomplexes has been demonstrated experimentally? Coenzyme Q (CoQ) is not a protein, but a small, hydrophobic molecule. Why is it important for the functioning of the electron-transport chain that CoQ is a hydrophobic molecule?

10. It is estimated that each electron pair donated by NADH leads to the synthesis of approximately three ATP molecules, whereas each electron pair donated by $FADH_2$ leads to the synthesis of approximately two ATP molecules. What is the underlying reason for the difference in yield for electrons donated by $FADH_2$ versus NADH?
11. Describe the main functions of the different components of the ATP synthase enzyme in the mitochondrion. A structurally similar enzyme is responsible for the acidification of lysosomes and endosomes. Given what you know about the mechanism of ATP synthesis, explain how this acidification might occur.
12. Much of our understanding of ATP synthase is derived from research on aerobic bacteria. What makes these organisms useful for this research? Where do the reactions of glycolysis, the citric acid cycle, and the electron-transport chain occur in these organisms? Where is the proton-motive force generated in aerobic bacteria? What other cellular processes depend on the proton-motive force in these organisms?

13. An important function of the inner mitochondrial membrane is to provide a selectively permeable barrier to the movement of water-soluble molecules and thus to generate different chemical environments on either side of the membrane. However, many of the substrates and products of oxidative phosphorylation are water soluble and must cross the inner membrane. How does this transport occur?
14. The Q cycle plays a major role in the electron-transport chain of mitochondria, chloroplasts, and bacteria. What is the function of the Q cycle, and how does it carry out this function? What electron-transport components participate in the Q cycle in mitochondria, in purple bacteria, and in chloroplasts?
15. True or false: Since ATP is generated in chloroplasts, cells capable of undergoing photosynthesis do not require mitochondria. Explain. Name and describe the idea that explains how mitochondria and chloroplasts are thought to have originated in eukaryotic cells.
16. Write the overall reaction of oxygen-generating photosynthesis. Explain the following statement: The O_2 generated by photosynthesis is simply a by-product of the pathway's generation of carbohydrates and ATP.
17. Photosynthesis can be divided into multiple stages. What are the stages of photosynthesis, and where does each occur within the chloroplast? Where is the sucrose produced by photosynthesis generated?

18. The photosystems responsible for absorption of light energy are each composed of two linked components, the reaction center and an antenna complex. What is the pigment composition and role of each component in the process of light absorption? What evidence exists that the pigments found in these components are involved in photosynthesis?
19. Photosynthesis in green and purple bacteria does not produce O_2. Why? How can these organisms still use photosynthesis to produce ATP? What molecules serve as electron donors in these organisms?
20. Chloroplasts contain two photosystems. What is the function of each? For linear electron flow, diagram the flow of electrons from photon absorption to NADPH formation. What does the energy stored in the form of NADPH synthesize?
21. The Calvin cycle reactions that fix CO_2 do not function in the dark. What are the likely reasons for this? How are these reactions regulated by light?
22. Rubisco, which may be the most abundant protein on Earth, plays a key role in the synthesis of carbohydrates in organisms that use photosynthesis. What is rubisco, where is it located, and what function does it serve?

CHAPTER 13

Moving Proteins into Membranes and Organelles

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

A three-dimensional reconstruction of the internal membranes of a yeast cell using scanning electron microscopy. The cell wall has been removed and the organelles highlighted with false color to reveal the endoplasmic reticulum (yellow), mitochondria (red), and nucleus (blue). Cell diameter is $3.5\ \mu m$.

[From D. Wei et al., 2012, "High-Resolution Three-Dimensional Reconstruction of a Whole Yeast Cell Using Focused-Ion Beam Scanning Electron Microscopy," *Biotechniques* **53**(1):41–48.]

OUTLINE

13.1 Targeting Proteins to and Across the ER Membrane
13.2 Insertion of Membrane Proteins into the ER
13.3 Protein Modifications, Folding, and Quality Control in the ER
13.4 Targeting of Proteins to Mitochondria and Chloroplasts
13.5 Targeting of Peroxisomal Proteins
13.6 Transport into and out of the Nucleus

A typical mammalian cell contains up to 10,000 different kinds of proteins; a yeast cell, about 5000. The vast majority of these proteins are synthesized by cytosolic ribosomes, and although many newly synthesized proteins remain within the cytosol (see Chapter 5), as many as half of the different kinds of proteins produced in a typical cell are delivered to one or another of the various membrane-bounded compartments of the cell. For example, many receptor proteins and transport proteins must be delivered to the plasma membrane, digestive enzymes and polypeptide signaling molecules must be directed to the cell surface for secretion from the cell, and enzymes such as RNA and DNA polymerases must be targeted to the nucleus. These and all the other proteins produced by a cell must reach their correct locations for the cell to function properly.

The delivery of newly synthesized proteins to their proper cellular destinations, usually referred to as *protein targeting* or *protein sorting*, encompasses two very different kinds of processes: **signal-based targeting** to a variety of organelles and **vesicle-based trafficking** in the secretory pathway. The first kind of process involves the targeting of a newly synthesized protein from the cytoplasm to an intracellular organelle. Targeting can occur during translation or soon after synthesis

of the protein is complete. For membrane proteins, targeting leads to insertion of the protein into the lipid bilayer of the membrane, whereas for water-soluble proteins, targeting leads to translocation of the entire protein across the membrane into the aqueous interior of the organelle. Proteins are sorted to the endoplasmic reticulum (ER), mitochondria, chloroplasts, peroxisomes, and nucleus by this general process (Figure 13-1).

FIGURE 13-1 Overview of major protein-sorting pathways in eukaryotes. All nuclear DNA–encoded mRNAs are translated on cytosolic ribosomes (step 1), but proteins can be directed to different intracellular locations according to targeting signals within the polypeptide sequence. *Left* (secretory pathway): Ribosomes synthesizing nascent secretory proteins are directed to the rough endoplasmic reticulum (ER) by an ER signal sequence (pink; step 2). After translation is completed

on the ER, these proteins can move by vesicle-based transport processes to the Golgi complex and on to the plasma membrane or to lysosomes. The vesicle-based processes underlying the secretory pathway (shaded box) are discussed in Chapter 14. *Right* (signal-based targeting): Synthesis of proteins that contain no targeting sequence are released into the cytosol and remain there (step 3). Proteins with an organelle-specific targeting sequence (pink) are first released into the cytosol but are then imported into mitochondria, chloroplasts, peroxisomes, or the nucleus (steps 4–7). Mitochondrial and chloroplast proteins typically pass through the outer and inner membranes to enter the matrix or stromal space, respectively. Other proteins are sorted to other subcompartments of these organelles by additional sorting steps. Nuclear proteins enter and exit through visible pores in the nuclear envelope.

The second general sorting process, known as the **secretory pathway**, involves transport of proteins from the ER to their final destination within membrane-enclosed vesicles. For many proteins, including those that make up the extracellular matrix, the final destination is the outside of the cell (hence the name); integral membrane proteins are also transported to the Golgi complex, lysosomes, and plasma membrane by this process. The secretory pathway begins in the ER; thus all proteins slated to enter the secretory pathway are initially targeted to this organelle.

Targeting to the ER usually involves *nascent* proteins still in the process of being synthesized on a ribosome. Newly made proteins are thus extruded from the ribosome directly into the ER membrane. Once translocated across the ER membrane, proteins are assembled into their native conformation by protein-folding catalysts present in the lumen of the ER. Indeed, the ER is the location where about one-third of the proteins in a typical cell fold into their native conformations, and most of the resident ER proteins either directly or indirectly contribute to the folding process. As part of the folding process, proteins also undergo specific post-

translational modifications in the ER. These processes are monitored carefully, and only after their folding and assembly is complete are proteins permitted to be transported out of the ER to other destinations along the secretory pathway. Proteins whose final destination is the lysosome, plasma membrane, or cell exterior are transported along the secretory pathway by the action of small vesicles that bud from the membrane of one organelle and then fuse with the membrane of another (see Figure 13-1 [shaded box] and Figure 14-1). We discuss vesicle-based protein trafficking in Chapter 14 because mechanistically it differs significantly from non-vesicle-based protein targeting to intracellular organelles.

In this chapter, we examine how proteins are targeted to five intracellular organelles: the ER, mitochondria, chloroplasts, peroxisomes, and nucleus. Two features of this protein-targeting process were initially quite baffling: How could a given protein be directed to only one specific membrane, and how could relatively large hydrophilic protein molecules be translocated across a hydrophobic membrane without disrupting the function of the bilayer as a barrier to ions and small molecules? Using a combination of biochemical purification methods and genetic screens for identifying mutants unable to execute particular translocation steps, cell biologists have identified many of the cellular components required for translocation across each of the different intracellular membranes. In addition, many of the major translocation processes in the cell have been reconstituted by incorporating their purified protein components into artificial lipid bilayers, using in vitro systems that can be freely manipulated experimentally.

These studies have shown that, despite some variations, the same basic mechanisms govern protein sorting to all the various intracellular organelles. As shown in Table 13-1, the mechanism of targeting to five organelles considered in this chapter can be described by four basic elements. (1) The information to target a protein to a particular organelle destination is encoded within the amino acid sequence of the protein itself, usually within a sequence of about 20 amino acids, known generically as a **targeting sequence**; these sequences are also called **signal sequences** or **signal peptides**. Such targeting sequences are usually located at the N-terminus of a protein and are thus the first part of the protein to be synthesized. More rarely, targeting sequences are located at either the C-terminus or within the interior of a protein sequence. (2) Each organelle carries a set of receptor proteins that bind (directly or indirectly) only to specific kinds of targeting sequences, thus ensuring the specificity of targeting. (3) Once a protein containing a targeting sequence has interacted with the corresponding receptor, the polypeptide chain is transferred to some kind of *translocation channel* that allows the protein to pass into or through the membrane bilayer. (4) Finally, the unidirectional transfer of a protein into an organelle, without its sliding back out into the cytoplasm, is usually achieved by coupling translocation to an energetically favorable process such as hydrolysis of GTP or ATP. In some cases, proteins are sorted further to reach a subcompartment within the target organelle; such sorting depends on yet other signal sequences and other receptor proteins.

TABLE 13-1 • Targeting Sequences Direct Proteins from the Cytosol to Organelles

Target	Targeting	Receptor	Translocation	Energy Source

Organelle	Sequence		Channel	
Endoplasmic reticulum (lumen)	At N-terminus, 6–12 hydrophobic amino acids, often preceded by one or more basic amino acids (Arg, Lys)	SRP (ribonucleoprotein complex associated with ribosome) and SRP receptor in the ER membrane; SRP and SRP receptor are GTPases	Sec61 complex; proteins translocate as unfolded chain, as channel remains sealed to small molecules	Translation elongation powered by GTP hydrolysis
Mitochondrion[i] (matrix)	At N-terminus an amphipathic helix, 20–50 residues in length, with Arg and Lys residues on one side and hydrophobic residues on the other	Tom20/22 import receptor in the outer mitochondrial membrane	Channels composed of Tom40 in the outer mitochondrial membrane and Tim23/17 in the inner membrane	ATP hydrolysis by Hsp70 in the matrix
Chloroplast[i] (stroma)	At N-terminus, but no common motifs; generally rich in Ser, Thr, and small hydrophobic residues and	Toc159 and Toc34, GTPases in the outer membrane	Channels composed Toc75 in the outer membrane and Tic20 in the inner membrane	ATP hydrolysis by Hsp70 in the stroma

	poor in Glu and Asp			
Peroxisome (matrix)	PTS1 signal (Ser-Lys-Leu) at extreme C-terminus; PTS2 signal at N-terminus	Pex5, which cycles between the cytoplasm and peroxisomal membrane	A complex of Pex5 and the peroxisomal membrane protein Pex14; cargo proteins can be transported in a folded state	ATP hydrolysis coupled to ubiquitination and deubiquitination of Pex5
Nucleus (nucleoplasm)	NLS sequences can function at any location within a protein sequence; a common motif includes a short segment rich in Lys and Arg residues	Nuclear transport receptors, which cycle between the cytoplasm and the nuclear interior	Central channel of the nuclear pore complex which is filled with a fluidlike phase of FG-repeat proteins; proteins and RNA can traverse in folded state when bound to a nuclear transport receptor	GTP hydrolysis coupled to cycling of Ran GTPase into and out of the nucleus

[i]Targeting to subcompartments of the mitochondria (such as the inner membrane) and the chloroplast (such as the thylakoid) require additional targeting sequences, receptors, and translocation channels as discussed in this chapter.

In the first part of the chapter, we cover targeting of proteins to the ER, including the post-translational modifications that proteins undergo as they enter the secretory pathway. Targeting of proteins to the ER is the best understood example of protein targeting and will serve as a model of the process in general. We then describe targeting of proteins to mitochondria, chloroplasts, and peroxisomes. Finally, we cover the transport of proteins into and out of the nucleus through nuclear pores.

An important consequence of knowing the nature of the different kinds of targeting sequences is that from just the amino acid sequence encoded by a gene it is possible to reliably deduce the final cellular location of the gene product. Indeed, the cellular location of most proteins encoded by the human genome has been accurately predicted using the information on the nature of different kinds of targeting sequences that we will discuss in this chapter.

13.1 Targeting Proteins to and Across the ER Membrane

All eukaryotic cells have an endoplasmic reticulum (ER). The ER is a convoluted organelle, made up of tubules and flattened sacs, whose membrane is continuous with the membrane of the nucleus. The ER usually has a very large surface area, and its membrane is where cellular lipids are synthesized (see Chapter 10). The ER is also where most membrane proteins are assembled, including those of the plasma membrane and the membranes of the lysosomes, ER, and Golgi complex. In addition, all soluble proteins that will eventually be secreted from the cell — as well as those destined for the lumen of the ER, Golgi complex, or lysosomes — are initially delivered to the ER lumen (see Figure 13-1). Since the ER plays such an important role in protein secretion, we refer to the pathway of protein trafficking that flows through the ER as the *secretory pathway*. For simplicity, we will refer to all proteins initially targeted to the ER as *secretory proteins*, but keep in mind that not all proteins that are targeted to the ER are actually secreted from the cell.

In this first section of the chapter, we discuss how proteins are initially identified as secretory proteins and how such proteins are translocated across the ER membrane. We deal first with soluble proteins — those that pass all the way through the ER membrane, into the lumen. In the next section, we discuss integral membrane proteins, which are inserted into the ER membrane.

Pulse-Chase Experiments with Purified ER Membranes Demonstrated That Secreted Proteins Cross the ER Membrane

Although all cells secrete a variety of proteins (e.g., extracellular matrix proteins), certain types of cells are specialized for secretion of large amounts of specific proteins. Pancreatic acinar cells, for instance, synthesize large quantities of several digestive enzymes, which are secreted into ductules that lead to the intestine. Because such secretory cells contain the organelles of the secretory pathway (e.g., ER and Golgi complex) in great abundance, they have been widely used in studying this pathway, including the initial steps that occur at the ER membrane.

The sequence of events that occur immediately after the synthesis of a secretory protein was first elucidated by pulse-chase experiments with pancreatic acinar cells. In these experiments, radioactively labeled amino acids were incorporated into secretory proteins as they were synthesized on ribosomes bound to the surface of the ER. The portion of the ER that receives proteins entering the secretory pathway is known as the **rough ER** because it is so densely studded with ribosomes that its surface appears morphologically distinct from other ER membranes (Figure 13-2). From these experiments, it became clear that during or immediately after their synthesis on the

ribosome, secretory proteins translocate across the ER membrane into the lumen of the ER.

FIGURE 13-2 Structure of the rough ER. (a) Electron micrograph of ribosomes attached to the rough ER in a pancreatic acinar cell. Most of the proteins

synthesized by this type of cell are secretory proteins and are formed on membrane-attached ribosomes. A few unattached (free) ribosomes are evident; presumably, these ribosomes are synthesizing cytosolic or other nonsecretory proteins. (b) Schematic representation of protein synthesis on the ER. Note that membrane-bound and free cytosolic ribosomes are identical. Membrane-bound ribosomes are recruited to the ER during synthesis of a polypeptide containing an ER signal sequence.

To delineate the steps in the translocation process, it was necessary to isolate the ER from the rest of the cell. Isolation of intact ER, with its delicate lacelike structure and its interconnectedness with other organelles, is not feasible. However, scientists discovered that when cells are homogenized, the rough ER breaks up into small closed vesicles with ribosomes on the outside, termed **microsomes**, which retain most of the biochemical properties of the intact ER, including the capability of protein translocation. The experiments depicted in Figure 13-3, in which microsomes isolated from pulse-labeled cells were treated with a protease, demonstrate that although secretory proteins are synthesized on ribosomes bound to the cytosolic face of the ER membrane, the polypeptides produced by these ribosomes end up within the lumen of a microsome. Experiments such as these raised the question of how polypeptides are recognized as secretory proteins shortly after their synthesis begins and how a nascent secretory protein is threaded across the ER membrane.

FIGURE 13-3 Secretory proteins enter the ER lumen. Labeling experiments demonstrated that secretory proteins are localized to the ER lumen shortly after synthesis. Cells are incubated for a brief time with radiolabeled amino acids so that only newly synthesized proteins become labeled. The cells are then homogenized, fracturing the plasma membrane and shearing the rough ER into small vesicles called *microsomes*. Because they have bound ribosomes, microsomes have a much greater buoyant density than other membranous organelles and can be separated from them by a combination of differential and sucrose density-gradient centrifugation (see Chapter 4). The purified microsomes are treated with a protease in the presence or absence of a detergent. The labeled secretory proteins associated with the microsomes are digested by the protease only if the microsomal membrane is first destroyed by treatment with detergent. This finding indicates that the newly made proteins are inside the microsomes, equivalent to the lumen of the rough ER.

A Hydrophobic N-Terminal Signal Sequence Targets Nascent Secretory Proteins to the ER

After synthesis of a secretory protein begins on free ribosomes in the cytosol, a 16–30-residue ER targeting sequence in the nascent protein directs the ribosome to the ER membrane and initiates translocation of the growing polypeptide across the ER membrane (see Figure 13-1, *left*). An ER targeting sequence, located at the N-terminus of the protein, is usually known as a *signal sequence*. The signal sequences of different secretory proteins all contain one or more positively charged amino acids adjacent to a continuous stretch of 6–12 hydrophobic residues (known as the *hydrophobic core*)

but otherwise have little in common. The signal sequence is cleaved from most secretory proteins while they are still elongating on the ribosome; thus signal sequences are usually not present in the mature proteins found in cells.

The hydrophobic core of an ER signal sequence is essential for its function. For instance, the specific deletion of several of the hydrophobic amino acids from a signal sequence or the introduction of charged amino acids into the hydrophobic core by mutation can abolish the ability of the N-terminus of a protein to function as a signal sequence. As a consequence, the modified protein remains in the cytosol, unable to cross the ER membrane into the lumen. Conversely, signal sequences can be added to normally cytosolic proteins using recombinant DNA techniques. Provided the added sequence is sufficiently long and hydrophobic, such a modified cytosolic protein can acquire the ability to be translocated into the ER lumen. The hydrophobic residues in the core of an ER signal sequence form a binding site that is critical for the interaction of the signal sequence with the machinery responsible for targeting the protein to the ER membrane.

Biochemical studies using a cell-free protein-synthesizing system, mRNA encoding a secretory protein, and microsomes stripped of their own bound ribosomes have elucidated how ER signal sequences function during protein translocation. Initial experiments with this system demonstrated that a typical secretory protein is incorporated into microsomes and has its signal sequence

removed only if the microsomes are present during protein synthesis. If instead of being present during translation, the addition of microsomes to the system is delayed until after protein synthesis is completed, no protein transport into the microsomes occurs (Figure 13-4). Subsequent experiments were designed to determine the precise stage of protein synthesis at which microsomes must be present in order for translocation to occur. In these experiments, microsomes were added to the reaction mixtures at different times after protein synthesis had begun. These experiments showed that microsomes must be added before the first 70 or so amino acids are translated in order for the completed secretory protein to be localized in the microsomal lumen. At this point, the first 40 or so amino acids protrude from the ribosome, including the signal sequence that will later be cleaved off, and the next 30 or so amino acids are still buried within a channel in the ribosome (see Figure 5-34). Thus the transport of most secretory proteins into the ER lumen begins while the incompletely synthesized (nascent) protein is still bound to the ribosome, a process referred to as **cotranslational translocation**.

FIGURE 13-4 Translation and translocation occur simultaneously. Cell-free experiments demonstrate that translocation of secretory proteins into microsomes is coupled to translation. Treatment of microsomes with EDTA, which chelates Mg^{2+} ions, strips them of associated ribosomes, allowing isolation of ribosome-free microsomes, which are equivalent to ER membranes (see Figure 13-3). Protein synthesis is carried out in a cell-free system containing functional ribosomes, aminoacyl-tRNAs, ATP, GTP, and cytosolic enzymes, to which mRNA encoding a secretory protein is added. (a) When microsomes are added after synthesis of secretory proteins is complete, the

secretory proteins that have already been formed will not enter microsomes. (b) However, when microsomes are present during protein synthesis, secretory proteins will be translocated across the vesicle membrane and lose their signal sequences (resulting in a decrease in molecular weight) as they are synthesized.

Cotranslational Translocation Is Initiated by Two GTP-Hydrolyzing Proteins

Given that secretory proteins are synthesized in association with the ER membrane but not with any other cellular membrane, a signal-sequence recognition mechanism must target them there. The two key components in this targeting are the **signal recognition particle (SRP)** and its receptor. The SRP is a cytosolic ribonucleoprotein particle that transiently binds to both the ER signal sequence in a nascent protein and the large (60S) ribosomal subunit, forming a large complex. The SRP then targets the nascent protein–ribosome complex to the ER membrane by binding to the **SRP receptor**, which is located in the membrane.

The SRP is made up of six proteins bound to a 300-nucleotide RNA, which acts as a scaffold for the hexamer. One of the SRP proteins (P54) can be chemically cross-linked to ER signal sequences, which shows that this subunit is the one that binds to the signal sequence in a nascent secretory protein. A region of P54 known as the *M*

domain, containing many methionine and other amino acid residues with hydrophobic side chains, forms a cleft or groove whose inner surface is lined by hydrophobic side chains (Figure 13-5a). The hydrophobic core of the signal sequence binds to this cleft via hydrophobic interactions. Other polypeptides in the SRP interact with the ribosome or are required for protein translocation into the ER lumen.

FIGURE 13-5 Structure of the signal recognition particle (SRP). (a) The signal-sequence-binding domain: the bacterial Ffh protein is homologous to the portion of P54 that binds ER signal sequences in eukaryotes. This surface model shows the binding domain in Ffh, which contains a large cleft or groove lined with hydrophobic amino acids (yellow) whose side chains interact with signal sequences. (b) GTP- and receptor-binding domain: the structure of GTP bound to FtsY (the archaeal homolog of the α subunit of the SRP receptor) and Ffh subunits from *Thermus aquaticus* illustrate how the interaction between these proteins is controlled by GTP binding and hydrolysis. Ffh and FtsY each can bind to one molecule of GTP, and when they bind to each other, the two bound molecules of GTP fit in the interface

between the protein subunits and stabilize the dimer. Assembly of the pseudosymmetric dimer allows formation of two active sites for the hydrolysis of both bound GTP molecules.

[Part (a) Data from R. J. Keenan et al., 1998, *Cell* **94**:181, PDB ID 2ffh. Part (b) data from P. J. Focia et al., 2004, *Science* **303**:373, PDB ID 1okk.]

The SRP and the nascent polypeptide chain–ribosome complex bind to the ER membrane by docking with the SRP receptor, an integral protein of the ER membrane made up of two subunits: an α subunit and a smaller β subunit. Interaction of the SRP–nascent chain–ribosome complex with the SRP receptor is strengthened when both the P54 subunit of the SRP and the α subunit of the SRP receptor are bound to GTP. The structure of the SRP P54 subunit and the SRP receptor α subunit (FtsY) from the archaean *Thermus aquaticus* provides insight into how a cycle of GTP binding and hydrolysis can drive the binding and dissociation of these proteins. Figure 13-5b shows that P54 and FtsY, each bound to a single molecule of GTP, come together to form a pseudosymmetric heterodimer. Neither subunit alone contains a complete active site for the hydrolysis of GTP, but when the two proteins come together, they form two complete active sites that are capable of hydrolyzing both bound GTP molecules. Hydrolysis to GDP destabilizes the interface, causing disassembly of the dimer.

Figure 13-6 summarizes our current understanding of secretory protein synthesis and the role of the SRP and its receptor in this process. Hydrolysis of the bound GTP accompanies disassembly of the SRP and SRP receptor and initiates transfer of the nascent chain

and ribosome to a site on the ER membrane, where translocation can take place. After dissociating from each other, the SRP and its receptor each release their bound GDP, SRP is recycled back to the cytosol, and both are ready to initiate another round of interaction between ribosomes synthesizing nascent secretory proteins and the ER membrane.

FIGURE 13-6 Cotranslational translocation. Steps 1–2: Once the ER signal sequence emerges from the ribosome, it is bound by a signal recognition particle (SRP). Step 3: The SRP and the nascent polypeptide chain–ribosome complex bind to the SRP receptor in the ER membrane. This interaction is strengthened by the binding of GTP to both the SRP and its receptor. Step 4: Transfer of the nascent polypeptide–ribosome to the translocon leads to opening of this translocation channel to admit the growing polypeptide adjacent to the signal sequence. The hydrophobic signal sequence itself is transferred to a hydrophobic binding site next to the central pore. Both the SRP and SRP receptor, once dissociated from the translocon, hydrolyze their bound GTP and then are ready to initiate the insertion of another polypeptide chain. Step 5: As the polypeptide chain elongates, it passes through the translocon channel into the ER lumen. The signal peptidase, whose active site faces the

ER lumen, cleaves the signal peptide as soon as the recognition site enters the lumen. Step 6: The peptide chain continues to elongate as the mRNA is translated toward the $3'$ end. Because the ribosome is attached to the translocon, the growing chain is extruded through the translocon into the ER lumen. Steps 7 – 8: Once translation is complete, the ribosome is released, the remainder of the protein is drawn into the ER lumen, the translocon closes, and the protein assumes its native folded conformation.

What is the purpose of coupling GTP hydrolysis by SRP and SRP receptor to delivery of a signal sequence to the translocon — the channel across the membrane? It is clear that this GTP hydrolysis does not provide the motive energy for ongoing translocation since it occurs only at the initiation of the translocation process. The GTPase cycle depicted in Figure 13-6 appears to be analogous to the GTP hydrolysis coupled to the initiation of *translation* on the ribosome as depicted in Figure 5-36. By coupling to GTP hydrolysis, a complex macromolecular assembly reaction can be made more efficient by adding a proofreading step that can increase the fidelity of the reaction.

Passage of Growing Polypeptides Through the Translocon Is Driven by Translation

Once the SRP and its receptor have targeted a ribosome synthesizing a secretory protein to the ER membrane, the ribosome and nascent polypeptide chain are rapidly transferred to the **translocon**, a

complex of proteins that forms a channel embedded within the ER membrane. As translation continues, the elongating chain passes directly from the large ribosomal subunit into the central pore of the translocon. The large ribosomal subunit is aligned with the pore of the translocon in such a way that the growing chain is never exposed to the cytoplasm and is prevented from folding until it reaches the ER lumen (see Figure 13-6).

The translocon was first identified through mutations in the yeast gene encoding a protein called *Sec61α*, which caused a block in the translocation of secretory proteins into the lumen of the ER. Subsequently, three proteins, collectively called the *Sec61 complex*, were found to form the mammalian translocon: Sec61α, an integral membrane protein with 10 membrane-spanning α helices, and two smaller proteins, termed *Sec61β* and *Sec61γ*. Chemical cross-linking experiments in a cell-free translocation system — in which amino acid side chains from a nascent secretory protein became covalently attached to the Sec61α subunit — demonstrated that the translocating polypeptide chain comes into contact with the Sec61α protein, confirming its identity as the translocon pore (Figure 13-7).

FIGURE 13-7 Sec61α is a translocon component. Experiments using added chemical cross-linkers show that nascent secretory proteins come into close proximity of the translocon component Sec61α as they pass into the ER lumen. An mRNA encoding the N-terminal 70 amino acids of the secreted protein prolactin was translated in a cell-free system containing microsomes (see Figure 13-4b). The mRNA

lacked a chain-termination codon and contained one lysine codon near the middle of the sequence. The reaction mixtures contained a chemically modified lysyl-tRNA in which a light-activated cross-linking reagent was attached to the lysine side chain. Although the entire mRNA was translated, the completed polypeptide could not be released from the ribosome without a chain-termination codon and thus became "stuck" crossing the ER membrane. The reaction mixtures were then exposed to intense light, which caused the nascent polypeptide chain to become covalently bound to whatever proteins were near it in the translocon. When the experiment was performed using microsomes from mammalian cells, the nascent chain became covalently linked to Sec61α. Different versions of the prolactin mRNA were created so that the modified lysine residue would be placed at different distances from the ribosome; cross-linking to Sec61α was observed only when the modified lysine was positioned within the translocation channel. See T. A. Rapoport, 1992, *Science* **258**:931; and D. Görlich and T. A. Rapoport, 1993, *Cell* **75**:615.

When microsomes in the cell-free translocation system were replaced with reconstituted phospholipid vesicles containing only the SRP receptor and the Sec61 complex, nascent secretory proteins were translocated from their SRP-ribosome complex into the vesicles. This finding indicates that the SRP receptor and the Sec61 complex are the only ER-membrane proteins that are absolutely required for translocation. The energy derived from chain elongation at the ribosome appears to provide the driving force to push the polypeptide chain across the membrane in one direction.

The translocon must be able to allow passage of a polypeptide chain while remaining sealed to small molecules, such as ATP, in order to maintain the permeability barrier of the ER membrane. Furthermore, there must be some way to regulate the translocon so that it is closed in its default state, opening only when a nascent

polypeptide chain–ribosome complex is bound. A high-resolution structural model of the archaeal Sec61 complex shows how the translocon preserves the integrity of the membrane (Figure 13-8). The 10 transmembrane helices of Sec61α form a central channel through which the translocating polypeptide chain passes. Two different gating steps are required for Sec61α to accept a translocating polypeptide. The 10 transmembrane helices are organized into two 5-helix bundles. In the first gating step, the bundles hinge apart like an opening clamshell to expose a hydrophobic binding pocket for the hydrophobic core of the signal sequence at the open edge. The signal sequence binds to Sec61α with its N-terminus facing the cytosol and the elongating polypeptide doubling back through the central channel. The structural model of the Sec61 complex, which was isolated without a translocating peptide and is therefore presumed to be in a closed conformation, reveals a short helical peptide plugging the central channel. Biochemical studies of the Sec61 complex have shown that, in the absence of a translocating polypeptide, the peptide that forms the plug effectively seals the translocon to prevent the passage of ions and small molecules. In the second gating step, after the signal sequence has bound to the opened channel, the translocating peptide enters the central pore of the channel, forcing away the plug peptide and allowing translocation to proceed. The middle of the central pore is lined with hydrophobic isoleucine residues that in effect form a gasket, preventing leakage of small polar molecules around the translocating peptide even as translocation proceeds.

FIGURE 13-8 Structure of an archaeal Sec61 complex. The structure of the detergent-solubilized Sec61 complex from the archaeon *Methanocaldococcus jannaschii* (also known as the *SecY complex*) was determined by x-ray crystallography. (a) A side view shows the hourglass-shaped channel through the center of the pore. A ring of isoleucine residues at the constricted waist of the pore forms a gasket that keeps the channel sealed to small molecules even as a translocating polypeptide passes through the channel. When no translocating peptide is present, the channel is closed by a short helical plug (red). This plug moves out of the channel during translocation. In this view, the front half of protein has been removed to better show the pore. (b) A view looking through the center of the channel shows a region (on the left side) where helices may separate, allowing lateral passage of a hydrophobic transmembrane domain into the lipid bilayer.

[Data from B. van den Berg et al., 2004, *Nature* **427**:36–44, PDB ID 1rhz and 1rh5.]

As the growing polypeptide chain enters the lumen of the ER, the signal sequence is cleaved by *signal peptidase*, which is a transmembrane ER protein associated with the translocon (see Figure 13-6, step **5**). Signal peptidase recognizes a sequence on the C-terminal end of the hydrophobic core of the signal peptide and cleaves the chain specifically at this sequence once it has emerged into the luminal space of the ER. After the signal sequence has been

cleaved, the growing polypeptide moves through the translocon into the ER lumen. The translocon remains open until translation is complete and the entire polypeptide chain has moved into the ER lumen. After translocation is complete, the plug peptide reseals the translocon channel.

ATP Hydrolysis Powers Post-Translational Translocation of Some Secretory Proteins in Yeast

In most eukaryotes, secretory proteins enter the ER by cotranslational translocation. In yeast, however, some secretory proteins enter the ER lumen after translation has been completed. In such **post-translational translocation**, the translocating protein passes through the same Sec61 translocon that is used in cotranslational translocation. However, the SRP and SRP receptor are not involved in post-translational translocation, and in such cases a direct interaction between the translocon and the signal sequence of the completed protein appears to be sufficient for targeting to the ER membrane. In addition, the driving force for unidirectional translocation across the ER membrane is provided by an additional protein complex known as the *Sec63 complex* and a member of the Hsp70 family of molecular chaperones known as *BiP* (see Chapter 3 for further discussion of molecular chaperones). The tetrameric Sec63 complex is embedded in the ER membrane in the

vicinity of the translocon, whereas BiP is within the ER lumen. Like other members of the Hsp70 family, BiP has a peptide-binding domain and an ATPase domain. These chaperones bind and stabilize unfolded or partially folded proteins (see Figure 3-17).

The current model for post-translational translocation of a protein into the ER is outlined in Figure 13-9. Once the N-terminal segment of the protein enters the ER lumen, signal peptidase cleaves the signal sequence just as in cotranslational translocation (step **1**). Interaction of BiP·ATP with the luminal portion of the Sec63 complex causes hydrolysis of the bound ATP, producing a conformational change in BiP that promotes its binding to an exposed polypeptide chain (step **2**). Since the Sec63 complex is located near the translocon, BiP is thus activated at sites where nascent polypeptides can enter the ER. Certain experiments suggest that, in the absence of binding to BiP, an unfolded polypeptide can freely slide back and forth within the translocon channel. Such random sliding motions rarely result in the entire polypeptide's crossing the ER membrane. Binding of a molecule of BiP·ADP to the luminal portion of the polypeptide prevents backsliding of the polypeptide out of the ER. As further inward random sliding exposes more of the polypeptide on the luminal side of the ER membrane, successive binding of BiP·ADP molecules to the polypeptide chain acts as a ratchet, ultimately drawing the entire polypeptide into the ER within a few seconds (steps **3** and **4**). After a delay of some time, the BiP molecules spontaneously exchange their bound ADP for ATP, leading to release of the polypeptide, which can then fold

into its native conformation (steps 5 and 6). The recycled BiP·ATP is then ready for another interaction with Sec63. BiP and the Sec63 complex are also required for cotranslational translocation. The details of their role in this process are not well understood, but they are thought to act at an early stage of the process, such as the threading of the signal peptide into the pore of the translocon.

FIGURE 13-9 Post-translational translocation. This mechanism is fairly common in yeast and probably occurs occasionally in higher eukaryotes. Step 1: For yeast proteins that can be translocated post-translationally, the signal sequence of the fully translated protein can engage with the translocon, causing the signal sequence and N-terminal portion of the protein to enter the ER where the signal sequence is cleaved. Small arrows inside the

translocon represent the ability of the translocating polypeptide to slide randomly inward and outward. Step **2**: Within the lumen of the ER, BiP·ATP is converted into BiP·ADP by the Sec63 complex. BiP·ADP has a high affinity for binding to exposed hydrophobic segments of the translocating polypeptide. Once BiP·ADP is bound, the polypeptide is no longer free to slide out toward the cytosol but can still slide inward as shown by the inward pointing arrow. Steps **3**–**5**: BiP·ADP binds to successive segments of the polypeptide as they enter the ER, progressively ratcheting the polypeptide inward until it has fully entered the ER lumen. Step **6**: Relatively slow exchange of ATP for ADP regenerates BiP·ATP, which releases the translocated peptide, allowing it to complete folding in the ER lumen. See K. E. Matlack et al., 1997, *Science* **277**:938.

The overall reaction carried out by BiP is an important example of how the chemical energy released by the hydrolysis of ATP can power the mechanical movement of a protein across a membrane. As we will see, translocation of proteins into mitochondria and chloroplasts can be powered by ATP hydrolysis by ATPase chaperone proteins located inside these organelles and also typically occurs by post-translational translocation. This explains why ribosomes are typically not found bound to these other organelles, as they are to the rough ER.

KEY CONCEPTS OF SECTION 13.1

Targeting Proteins to and Across the ER Membrane

- Synthesis of secreted proteins, integral plasma-membrane proteins, and proteins destined for the ER, Golgi complex, or lysosome begins on cytosolic ribosomes, which become attached to the membrane of the ER, forming the rough ER (see Figure 13-1, *left*).
- The ER signal sequence on a nascent secretory protein is located at the N-terminus and contains a sequence of hydrophobic amino acids.

- In cotranslational translocation, the signal recognition particle (SRP) first recognizes and binds the ER signal sequence on a nascent secretory protein, then is bound in turn by an SRP receptor on the ER membrane, thereby targeting the nascent polypeptide chain–ribosome complex to the ER.
- The SRP and SRP receptor then mediate insertion of the nascent secretory protein into the translocon (Sec61 complex). Hydrolysis of two molecules of GTP by the SRP and its receptor cause the dissociation of SRP (see Figures 13-5 and 13-6). Coupling GTP hydrolysis to the loading of signal-sequence bearing proteins to the translocon is thought to increase the fidelity of this assembly reaction.
- As the ribosome attached to the translocon continues translation, the unfolded protein chain is extruded into the ER lumen.
- The translocon contains a central channel lined with hydrophobic residues that allows transit of an unfolded protein chain while remaining sealed to ions and small hydrophilic molecules. In addition, the channel is gated so that it is open only when a polypeptide is being translocated.
- In post-translational translocation, a completed secretory protein is targeted to the ER membrane by interaction of the signal sequence with the translocon. The polypeptide chain is then pulled into the ER by a ratcheting mechanism that requires ATP hydrolysis by the chaperone BiP, which stabilizes the entering polypeptide (see Figure 13-9).
- In both cotranslational and post-translational translocation, a signal peptidase in the ER membrane cleaves the ER signal sequence from a secretory protein soon after the N-terminus enters the lumen.

13.2 Insertion of Membrane Proteins into the ER

In previous chapters, we have encountered many of the vast array of integral membrane (transmembrane) proteins that are present throughout the cell. Each such protein has a unique orientation with respect to the membrane's phospholipid bilayer. Integral membrane proteins located in the ER, Golgi complex, and lysosomes, as well as in the plasma membrane, which are all synthesized on the rough ER, remain embedded in the membrane as they move to their final destinations along the same pathway that is followed by soluble secretory proteins (see Figure 13-1, *left*). During this transport, the orientation of a membrane protein is preserved; that is, the same segments of the protein always face the cytoplasmic side of the membrane, whereas other segments always face in the opposite direction, which could be considered the exoplasmic side of the membrane. Thus the final orientation of these membrane proteins is established during their biosynthesis on the ER membrane. As we will see in this section, insertion of membrane proteins into the ER membrane employs the same mechanism that has already been described for entry of soluble secretory proteins into the lumen of the ER. Membrane proteins first engage the translocon, made up of the Sec61 complex, by the interaction of a hydrophobic signal sequence with SRP and SRP receptor. Once engaged with the translocon, hydrophilic portions of the membrane protein can enter the ER lumen by translocation, whereas the hydrophobic portions

become embedded in the ER membrane by lateral opening of the translocon gate. The final topological orientation of membrane segments and hydrophilic regions of a membrane protein depends on the arrangement of hydrophobic sequences and neighboring positively charged amino acid residues. These sequences, known collectively as **topogenic sequences**, direct the membrane insertion and orientation of various classes of integral membrane proteins.

Several Topological Classes of Integral Membrane Proteins Are Synthesized on the ER

The **topology** of a membrane protein refers to the number of times its polypeptide chain spans the membrane and the orientation of those membrane-spanning segments within the membrane. The key elements of a protein that determine its topology are the membrane-spanning segments themselves, which are usually α helices containing 20–25 hydrophobic amino acids that contribute to energetically favorable interactions within the hydrophobic interior of the phospholipid bilayer.

Most integral membrane proteins fall into one of the five topological classes illustrated in Figure 13-10. Topological classes I, II, III, and the tail-anchored proteins are **single-pass membrane proteins**, which have only one membrane-spanning α-helical segment. Type I

proteins have a cleaved N-terminal ER signal sequence and are anchored in the membrane with their hydrophilic N-terminal region on the luminal face (also known as the *exoplasmic face*) and their hydrophilic C-terminal region on the cytosolic face. Type II proteins do not contain a cleavable ER signal sequence and are oriented with their hydrophilic N-terminal region on the cytosolic face and their hydrophilic C-terminal region on the exoplasmic face (i.e., opposite to type I proteins). Type III proteins have a hydrophobic membrane-spanning segment at their N-terminus and thus have the same orientation as type I proteins, but do not contain a cleavable signal sequence. Finally, tail-anchored proteins have a hydrophobic segment at their C-terminus that spans the membrane. These different topologies reflect distinct mechanisms used by the cell to establish the orientation of transmembrane segments, as we will see shortly.

FIGURE 13-10 Classes of ER membrane proteins. Five topological classes of integral membrane proteins are synthesized on the rough ER, as is a sixth type tethered to the membrane by a phospholipid anchor. These membrane proteins are classified by their

orientation in the membrane and the types of signals they contain to direct them there. In the integral membrane proteins, hydrophobic segments of the protein chain form α helices embedded in the membrane bilayer; the regions outside the membrane are hydrophilic and fold into various conformations. All type IV proteins have multiple transmembrane α helices. The type IV topology depicted here corresponds to that of G protein–coupled receptors: seven α helices, the N-terminus on the exoplasmic side of the membrane, and the C-terminus on the cytosolic side. Other type IV proteins may have a different number of helices and various orientations of the N-terminus and C-terminus. See E. Hartmann et al., 1989, *P. Natl. Acad. Sci. USA* **86**:5786; and C. A. Brown and S. D. Black, 1989, *J. Biol. Chem.* **264**:4442.

The proteins forming topological type IV contain two or more membrane-spanning segments and are sometimes called **multipass membrane proteins**. For example, many of the membrane transport proteins discussed in Chapter 11 and the numerous G protein–coupled receptors covered in Chapter 15 belong to this class.

When considering the mechanism of assembly of integral membrane proteins it is often useful to consider the topology of an individual membrane spanning segment. An N_{cyto}-C_{exo} transmembrane segment is oriented with the N-terminal end facing the inside of the cytoplasm and the C-terminal end facing exoplasmic side of the membrane that would be the lumen of the ER or the topological equivalent that is the outside of the cell. The other possible orientation is N_{exo}-C_{cyto}. Thus the transmembrane span of a type I membrane protein is N_{exo}-C_{cyto}, whereas the transmembrane span of a type II protein is N_{cyto}-C_{exo}. Note that for a type IV protein

with multiple spans, the orientation strictly alternates between N_{cyto}-C_{exo} and N_{exo}-C_{cyto}.

Some lipid-anchored membrane proteins are also synthesized on the ER. These membrane proteins lack a hydrophobic membrane-spanning segment altogether; instead, they are linked to an amphipathic phospholipid anchor that is embedded in the membrane (Figure 13-10, *right*).

Internal Stop-Transfer Anchor and Signal-Anchor Sequences Determine Topology of Single-Pass Proteins

We begin our discussion of how membrane protein topology is determined with the insertion of integral membrane proteins that contain a single hydrophobic membrane-spanning segment. As we will see, three main types of topogenic sequences are used to direct proteins to the ER membrane and to orient them within it. We have already introduced one, the N-terminal signal sequence. The other two types of sequences, which we will introduce here, are internal sequences known as *stop-transfer anchor sequences* and *signal-anchor sequences*. Unlike signal sequences, these two types of internal topogenic sequences end up in the mature protein as membrane-spanning segments. However, the two types differ in their final orientation in the membrane.

Type I Proteins

In addition to an N-terminal signal sequence that targets them to the ER, all type I transmembrane proteins possess an internal hydrophobic sequence of approximately 22 amino acids, which becomes the membrane-spanning α helix. The N-terminal signal sequence of a nascent type I protein, like that of a soluble secretory protein, initiates cotranslational translocation of the protein through the combined action of the SRP and SRP receptor. Once the N-terminus of the growing polypeptide enters the lumen of the ER, the signal sequence is cleaved, and the growing polypeptide chain continues to be extruded across the ER membrane. However, when the sequence that will become a transmembrane domain enters the translocon, transfer of the protein through the channel stops and the transmembrane domain is allowed to move laterally from the channel into the membrane (Figure 13-11). The gating mechanism that allows lateral movement is the same as that for the opening of the translocon to accept the hydrophobic core of a signal sequence: two five-helix bundles of Sec61α hinge open to allow the hydrophobic transmembrane segment to move laterally past the hydrophobic signal-sequence-binding site through the opened edge of the translocon (see Figure 13-8). When the peptide exits the translocon in this manner, the hydrophobicity of the transmembrane segment anchors it in the hydrophobic interior of the membrane. Because such a sequence functions both to stop passage of the polypeptide chain through the translocon and to

become a hydrophobic transmembrane segment in the membrane bilayer, it is called a [stop-transfer anchor sequence (STA)](#).

FIGURE 13-11 Membrane insertion and orientation of type I single-pass transmembrane proteins. Step 1: After the nascent polypeptide chain–ribosome complex becomes associated with a translocon in the ER membrane, the N-terminal signal sequence is cleaved. This process occurs by the same mechanism as the one for soluble secretory proteins (see Figure 13-6). Steps 2–3: The chain is elongated until the hydrophobic stop-transfer anchor sequence is synthesized and enters the translocon, where it prevents the nascent chain from extruding farther into the ER lumen. Step 4: The stop-transfer anchor sequence moves laterally through a hydrophobic cleft between translocon subunits and ultimately becomes anchored in the phospholipid bilayer. At this time, the translocon probably closes. Step 5: As synthesis continues, the elongating chain may loop out into the cytosol through the small space between the ribosome and translocon. Step 6: When synthesis is complete, the ribosomal subunits are released into the cytosol, leaving the protein free to diffuse laterally in the membrane. See H. Do et al., 1996, *Cell* **85**:369; and W. Mothes et al., 1997, *Cell* **89**:523.

Once translocation is interrupted, translation continues at the ribosome, which is still anchored to the now unoccupied and closed

translocon. As the C-terminus of the protein chain is synthesized, it loops out on the cytosolic side of the membrane. When translation is complete, the ribosome is released from the translocon, and the C-terminus of the newly synthesized type I protein remains in the cytosol. Ultimately, the stop-transfer anchor sequence resides in the membrane in an N_{exo}-C_{cyto} orientation.

Support for this mechanism has come from studies in which cDNAs encoding various mutant receptors for human growth hormone (HGH) were expressed in cultured mammalian cells. The wild-type HGH receptor, a typical type I protein, is normally transported to the plasma membrane. However, a mutant receptor that has charged residues inserted into the single membrane-spanning segment, or that is missing most of this segment altogether, is translocated entirely into the ER lumen and is eventually secreted from the cell as a soluble protein. These kinds of experiments have established that the hydrophobic membrane-spanning segment of the HGH receptor, and of other type I proteins, functions both as a stop-transfer sequence and as a membrane anchor that prevents the C-terminus of the protein from crossing the ER membrane.

Type II and Type III Proteins

Unlike type I proteins, type II and type III proteins lack a cleavable N-terminal ER signal sequence. Instead, both possess a single internal hydrophobic **signal-anchor sequence (SA)** that functions as both an ER signal sequence and a membrane anchor. Recall that

type II and type III proteins have opposite orientations in the membrane (see Figure 13-10); this difference depends on the orientation that their respective signal-anchor sequences assume within the translocon. The internal signal-anchor sequence in type II proteins directs insertion of the nascent polypeptide chain into the ER membrane so that the N-terminus of the chain faces the cytosol, using the same SRP-dependent mechanism described for signal sequences (Figure 13-12a). However, the internal signal-anchor sequence does not have a recognition sequence for signal peptidase and therefore is *not* cleaved. Because of its hydrophobicity, the signal-anchor sequence can move laterally from the signal-sequence-binding site at the edge of the translocon directly into the phospholipid bilayer, where it functions as a membrane anchor. As elongation continues, the C-terminal region of the growing chain is extruded through the translocon into the ER lumen by cotranslational translocation.

FIGURE 13-12 Membrane insertion and orientation of type II and type III single-pass transmembrane proteins. (a) Type II proteins. Step 1: After the internal signal-anchor sequence is synthesized on a cytosolic ribosome, it is bound by an SRP (not shown), which binds the SRP receptor on the ER membrane. This process is similar to the targeting of soluble secretory proteins except that the hydrophobic signal sequence is not located at the N-terminus and is not subsequently cleaved. The nascent polypeptide chain becomes oriented in the translocon with its N-terminal portion toward the cytosol. This orientation is dictated by the positively charged residues shown N-terminal to the signal-anchor sequence. Step 2: As the chain is elongated and extruded into the lumen, the internal signal-anchor sequence moves laterally through a hydrophobic cleft between translocon subunits and anchors the chain in the phospholipid bilayer. Step 3: Once protein synthesis is complete, the C-terminus of the polypeptide is released into the lumen and the ribosomal subunits are released into the cytosol. (b) Type III proteins. Step 1: Insertion is by a process similar to that of type II proteins, except that positively charged residues on the C-terminal side of the signal-anchor sequence cause the transmembrane segment to be oriented within the translocon with its C-terminal portion toward the cytosol and the N-terminal end in the ER lumen. Note that when the signal-anchor segment engages with the translocon, the preceding hydrophilic segment is short enough to spontaneously pass through the translocon channel. Steps 2–3: Elongation of the C-terminal portion of the polypeptide chain is completed in the cytosol, and the ribosomal subunits are released. See M. Spiess and H. F. Lodish, 1986, *Cell* **44**:177; and H. Do et al., 1996, *Cell* **85**:369.

In the case of type III proteins, the signal-anchor sequence, which is located near the N-terminus, directs insertion of the nascent chain into the ER membrane with its N-terminus facing the lumen, in an orientation opposite to that of the signal-anchor in type II proteins. The signal-anchor sequence of type III proteins also functions like a stop-transfer sequence and prevents further extrusion of the elongating chain into the ER lumen (Figure 13-12b). Continued elongation of the chain C-terminal to the signal-anchor sequence proceeds as it does for type I proteins, with the hydrophobic

sequence eventually moving laterally out of the translocon to anchor the polypeptide in the ER membrane (see Figure 13-11).

The key difference between type II and type III proteins is the orientation of the hydrophobic transmembrane segment as it binds to the hydrophobic signal-sequence-binding site at the edge of Sec61α. The membrane span of a type II protein is oriented N_{cyto}-C_{exo} whereas the span of a type III protein is N_{exo}-C_{cyto}. The most important feature that determines whether a protein with a single transmembrane span will assume a type II or type III orientation is the length of the hydrophilic sequence that precedes the transmembrane span. If the hydrophilic segment is more than a few amino acids in length, the energetic cost of transferring this segment across the membrane is too great for the transmembrane segment to assume an N_{exo}-C_{cyto} orientation of a type III protein. The orientation of signal-anchor sequences that are preceded by only a few hydrophilic amino acids is determined by the arrangement of positively charged amino acids adjacent to one end or the other of the hydrophobic segment. These positively charged residues tend to remain on the cytosolic side of the membrane, rather than traversing the membrane into the ER lumen. Thus the position of the charged residues dictates the orientation of the signal-anchor sequence within the translocon as well as whether the rest of the polypeptide chain continues to pass into the ER lumen: type II proteins tend to have positively charged residues on the N-terminal side of their signal-anchor sequence, orienting the N-

terminus in the cytosol and allowing passage of the C-terminal side into the ER (see Figure 13-12a), whereas type III proteins tend to have positively charged residues on the C-terminal side of their signal-anchor sequence, which restrict the C-terminus to the cytosol (see Figure 13-12b). Note that the hydrophobic segment of a type II signal-anchor sequence assumes the same N_{cyto}-C_{exo} orientation as the signal sequence of a secreted protein and that in most respects these signal-anchor sequences behave exactly like signal sequences, although they are not cleaved.

A striking experimental demonstration of the importance of the flanking charge in determining orientation in the membrane is provided by neuraminidase, a type II protein in the surface coat of the influenza virus. Three arginine residues are located just N-terminal to the internal signal-anchor sequence in neuraminidase. Mutation of these three positively charged residues to negatively charged glutamate residues causes neuraminidase to acquire the reverse orientation. Similar experiments have shown that other proteins, with either type II or type III orientation, can be made to "flip" their orientation in the ER membrane by mutating charged residues that flank the internal signal-anchor segment.

Tail-Anchored Proteins

For all the topological classes of proteins we have considered so far, membrane insertion begins when the SRP recognizes a hydrophobic

topogenic sequence as it emerges from the ribosome. Recognition of tail-anchored proteins, which have a single hydrophobic topogenic sequence at the C-terminus, presents a unique challenge because the hydrophobic C-terminus becomes available for recognition only after translation has been completed and the protein has been released from the ribosome. Insertion of tail-anchored proteins into the ER membrane does not employ an SRP, SRP receptor, or the translocon, but instead depends on a pathway dedicated to this purpose, as depicted in Figure 13-13. This pathway involves a dimer of an ATPase known as *Get3*, which binds to the C-terminal hydrophobic segment of a tail-anchored protein. The Get3 dimer has two ATP-binding sites at the dimer interface in a structure that is similar to the two GTP-binding sites in the heterodimeric interface between SRP and SRP receptor shown in Figure 13-5b. The complex of a Get3 dimer bound to a tail-anchored protein is recruited to the ER by a dimeric integral membrane receptor known as *Get1/Get2*. The tail-anchored protein is released from Get3, and the transmembrane portion of Get1/Get2 participates in the insertion of the tail-anchor into the ER membrane. This process is mechanistically similar to the targeting of type II and type III signal-anchor sequences to the ER by the SRP and SRP receptor; the underlying structural similarity indicates that the mechanism of targeting is fundamentally related, despite the fact that Get3 couples targeting of tail-anchored proteins to ATP hydrolysis, whereas SRP couples protein targeting to GTP hydrolysis.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 13-13 Insertion of tail-anchored proteins. For C-terminal tail-anchored proteins, the hydrophobic C-terminus is not available for membrane insertion until protein synthesis is complete and the protein has been released from the ribosome. Step **1**: Dimeric Get3 contains a hydrophobic binding pocket at the interface between dimer subunits and Get3 in an ATP-bound state binds to the hydrophobic C-terminal tail of the protein. This binding reaction is facilitated by a complex of three other proteins, Sgt2, Get4, and Get5, which sequester the hydrophobic C-terminal tail before transferring it to Get3·ATP (not shown). Step **2**: The ternary complex Get3·ATP bound to the protein docks onto the dimeric Get1/Get2 receptor, which is embedded in the ER membrane. Step **3**: In succession, ATP is hydrolyzed and ADP is released from Get3. At the same time, the hydrophobic C-terminal tail is released from Get3 and ultimately becomes embedded in the ER membrane in a process that is facilitated by Get1/Get2. Step **4**: Get3 binds to ATP and Get3·ATP is released from Get1/Get2 in a soluble form, ready for another round of binding to a hydrophobic C-terminal tail.

Type IV (Multipass) Proteins

As described in Chapter 11, many physiologically important proteins, such as channel proteins, membrane transporters and pumps, and some receptor proteins, can contain 12 or more membrane-spanning α helices. Although their three-dimensional structure can be quite complex, the membrane topology of multipass proteins can usually be deduced from the same principles used to predict the topology of single-pass proteins. Figure 13-14 summarizes the arrangements of topogenic sequences in single-pass and multipass transmembrane proteins. Two key principles govern the assembly of the vast majority of multipass proteins: (1) the membrane-spanning segments pass from the translocon into the membrane cotranslationally in the sequential order by which they emerge from the ribosome and (2) the first topogenic segment engages the translocon in an SRP and SRP receptor-dependent manner as for single-pass proteins, whereas all subsequent transmembrane segments engage the translocon independently of SRP. Based on these principles, the first transmembrane segment of a multipass protein acts as a topogenic sequence in the ways that we have already discussed for type I, type II, and type III proteins. Once the orientation of the first transmembrane segment is established (N_{exo}-C_{cyto} as with type I and type III proteins or N_{cyto}-C_{exo} as for type II proteins), each subsequent transmembrane segment assumes the opposite orientation as the one before. Thus an N_{exo}-C_{cyto} transmembrane segment is always followed by an N_{cyto}-C_{exo}

transmembrane segment and an N_{cyto}-C_{exo} transmembrane segment is always followed by an N_{exo}-C_{cyto} transmembrane segment. This strict alternation of orientation is a simple consequence of the fact that the hydrophilic segments cannot move across the membrane unless threaded through the channel of the translocon. If a multipass protein has an *even* number of transmembrane α helices, its N-terminus and C-terminus will be oriented toward the same side of the membrane (Figure 13-14d). Conversely, if a type IV protein has an *odd* number of α helices, its two ends will have opposite orientations (Figure 13-14e).

FIGURE 13-14 Topogenic sequences determine the orientation of ER membrane proteins. Topogenic sequences are shown in red; soluble, hydrophilic sequences in blue. The internal topogenic sequences form transmembrane α helices that anchor proteins or segments of proteins in the membrane. (a) Type I proteins contain a cleaved signal sequence and a single internal stop-transfer anchor (STA) sequence. (b, c) Type II and type III proteins contain a single internal signal-anchor (SA) sequence. The difference in the orientation of these protein types depends largely on whether there is a high density of positively charged amino

acids (+ + +) on the N-terminal side (type II) or on the C-terminal side of the SA sequence (type III). (d, e) Nearly all multipass proteins lack a cleavable signal sequence, as depicted in the examples shown here. Type IV-A proteins, whose N-terminus faces the cytosol, begin with an SA sequence similar to a type II protein. Type IV-B proteins, whose N-terminus faces the lumen, begin with an SA sequence similar to a type III protein. After the first topogenic sequence all subsequent transmembrane segments insert into the membrane with the opposite polarity as the segment before.

Type IV Proteins with N-Terminus in the Cytosol

Among the multipass proteins whose N-terminus extends into the cytosol are the various glucose transporters (GLUTs) and most ion-channel proteins, discussed in Chapter 11. In these proteins, the hydrophobic segment closest to the N-terminus functions like the internal signal-anchor sequence of a type II protein and is inserted into the ER membrane with an N_{cyto}-C_{exo} orientation (see Figure 13-12a). As the nascent chain following the transmembrane segment elongates, it moves through the translocon until the second hydrophobic segment is formed. This helix prevents further extrusion of the nascent chain through the translocon; thus its function is similar to that of the stop-transfer anchor sequence in a type I protein (see Figure 13-11).

After synthesis of the first two transmembrane α helices, both ends of the nascent chain face the cytosol, and the loop between them extends into the ER lumen. As the C-terminus of the nascent chain then continues to grow into the cytosol, as it does in synthesis of type III proteins, the ribosome remains attached to the translocon,

and hydrophobic sequences that subsequently emerge from the ribosome are threaded into the translocon without the need for the SRP and the SRP receptor. As new hydrophobic topogenic sequences engage the translocon, the previously engaged sequences move laterally out of the translocon using the same mechanism as for type I, type II, and type III membrane proteins.

Type IV Proteins with N-Terminus in the Exoplasmic Space

The large family of G protein–coupled receptors, all of which contain seven transmembrane α helices, constitute the most numerous type IV-B proteins, whose N-terminus extends into the exoplasmic space. In these proteins, the hydrophobic transmembrane segment closest to the N-terminus is often followed by a cluster of positively charged amino acids, like a type III signal-anchor sequence (see Figure 13-12b). As a result, the nascent polypeptide chain is inserted into the translocon with the N-terminus extending into the lumen (see Figure 13-14e). As the chain is elongated, it is inserted into the ER membrane in alternating orientation, as just described for type IV-A proteins.

A Phospholipid Anchor Tethers Some Cell-Surface Proteins to the Membrane

Some cell-surface proteins are anchored to the phospholipid bilayer not by a sequence of hydrophobic amino acids, but by a covalently attached amphipathic molecule, *glycosylphosphatidylinositol (GPI)* (Figure 13-15a; see also Chapter 7). These proteins are synthesized and initially anchored to the ER membrane exactly like type I transmembrane proteins, with a cleaved N-terminal signal sequence and an internal stop-transfer anchor sequence directing the process (see Figure 13-11). However, a short sequence of amino acids in the luminal domain, adjacent to the membrane-spanning domain, is recognized by a transamidase located within the ER membrane. This enzyme simultaneously cleaves off the original stop-transfer anchor sequence and transfers the luminal portion of the protein to a preformed GPI anchor in the membrane (Figure 13-15b).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 13-15 GPI-anchored proteins. (a) Structure of a glycosylphosphatidylinositol (GPI) molecule from yeast. The hydrophobic portion of the molecule is composed of fatty acyl chains, whereas the polar (hydrophilic) portion is composed of carbohydrate residues and phosphate groups. In other organisms, both the length of the acyl chains and the carbohydrate moieties may vary somewhat from the structure shown. (b) Formation of GPI-anchored proteins in the ER membrane. The protein is synthesized and initially inserted into the ER membrane like a type I

transmembrane protein, as shown in Figure 13-11. A specific transamidase simultaneously cleaves the precursor protein within the exoplasmic-facing domain, near the stop-transfer anchor sequence (red), and transfers the carboxyl group of the new C-terminus to the terminal amino group of a preformed GPI anchor. See C. Abeijon and C. B. Hirschberg, 1992, *Trends Biochem. Sci.* **17**:32; and K. Kodukula et al., 1992, *P. Natl. Acad. Sci. USA* **89**:4982.

Why change one type of membrane anchor for another? Attachment of the GPI anchor, which results in removal of the cytosol-facing hydrophilic domain from the protein, can have several consequences. Proteins with GPI anchors, for example, can diffuse relatively rapidly in the plane of the phospholipid bilayer. In contrast, many proteins anchored by membrane-spanning α helices are impeded from moving laterally in the membrane because their cytosol-facing segments interact with the cytoskeleton. In addition, the GPI anchor targets the attached protein to the apical domain of the plasma membrane (instead of the basolateral domain) in certain polarized epithelial cells, as we discuss in Chapter 14.

The Topology of a Membrane Protein Can Often Be Deduced from Its Sequence

As we have seen, various topogenic sequences in integral membrane proteins synthesized on the ER govern the interaction of the nascent polypeptide chain with the translocon. When scientists begin to

study a protein of unknown function, the identification of potential topogenic sequences within the corresponding gene sequence can provide important clues about the protein's topological class and function. Suppose, for example, that the gene for a protein known to be required for a cell-to-cell signaling pathway contains nucleotide sequences that encode an apparent N-terminal signal sequence and an internal hydrophobic sequence. These findings suggest that the protein is a type I integral membrane protein and therefore may be a cell-surface receptor for an extracellular ligand. Furthermore, the implied type I topology suggests that the N-terminal segment that lies between the signal sequence and the internal hydrophobic sequence probably constitutes the extracellular domain with a role in ligand binding, whereas the C-terminal segment that lies after the internal hydrophobic sequence is probably cytosolic and may play a role in intracellular signaling.

Identification of topogenic sequences requires a way to scan sequence databases for segments that are sufficiently hydrophobic to be either signal sequences or transmembrane anchor sequences. Topogenic sequences can often be identified with the aid of computer programs that generate a **hydropathy profile** for the protein of interest. The first step is to assign a value known as the *hydropathic index* to each amino acid in the protein. By convention, hydrophobic amino acids are assigned positive values and hydrophilic amino acids negative values. Although different scales for the hydropathic index exist, all assign the most positive values to

amino acids with side chains made up of mostly hydrocarbon residues (e.g., phenylalanine and methionine) and the most negative values to charged amino acids (e.g., arginine and aspartate). The second step is to identify long segments of sufficient overall hydrophobicity to be N-terminal signal sequences or internal stop-transfer anchor sequences and signal-anchor sequences. To accomplish this, the total hydropathic index for each segment of 20 consecutive amino acids is calculated along the entire length of the protein. Plots of these calculated values against position in the amino acid sequence yield a hydropathy profile.

Figure 13-16 shows the hydropathy profiles for three different membrane proteins. The prominent peaks in such plots identify probable topogenic sequences as well as their positions and approximate lengths. For example, the hydropathy profile of the human growth hormone receptor reveals the presence of both a hydrophobic signal sequence at the extreme N-terminus of the protein and an internal hydrophobic stop-transfer anchor sequence (Figure 13-16a). On the basis of this profile, we can deduce, correctly, that the HGH receptor is a type I integral membrane protein. The hydropathy profile of the asialoglycoprotein receptor, a cell-surface protein that mediates removal of abnormal extracellular glycoproteins, reveals a prominent internal hydrophobic signal-anchor sequence, but gives no indication of a hydrophobic N-terminal signal sequence (Figure 13-16b). Thus we can predict that the asialoglycoprotein receptor is a type II or type III membrane protein. Because the N-terminal segment of the asialoglycoprotein

receptor contains 30 hydrophilic residues that could not move across the membrane without a signal sequence to initiate engagement with the translocon, we can deduce that this segment must remain in the cytosol and we can correctly predict that this is a type II protein.

FIGURE 13-16 Hydropathy profiles for three types of proteins. Hydropathy profiles can identify likely topogenic sequences in integral membrane proteins. They are generated by plotting the total hydrophobicity of each segment of 20 contiguous amino acids along the length of a protein. Positive values indicate relatively hydrophobic portions of the protein; negative values relatively hydrophilic portions. Probable hydrophobic topogenic sequences are marked. (a) The human growth hormone receptor evidently has two topogenic sequences, a signal sequence at the N-terminus and an internal hydrophobic stop-transfer sequence. Note that the membrane-spanning stop-transfer sequence is significantly more hydrophobic than the signal sequence, which is typically the case. From this arrangement it would be possible to correctly deduce that this is a type I membrane protein with an N-terminal domain that binds the growth hormone. (b) The asialoglycoprotein receptor has a single hydrophobic topogenic sequence. This sequence can be correctly predicted to be a signal-anchor sequence for a type II protein because it is preceded by a hydrophilic segment of 30 amino acids. As a type II protein, the C-terminal domain is predicted to be the asialoglycoprotein binding domain. The complex profiles for multipass (type IV) proteins,

such as GLUT1 in part (c), must often be supplemented with other analyses to determine the topology of these proteins.

The hydropathy profile of the GLUT1 glucose transporter, a multipass transmembrane protein, shows the presence of many segments that are sufficiently hydrophobic to be membrane-spanning helices (Figure 13-16c). The complexity of this profile illustrates the difficulty both in predicting the orientation of the first topogenic sequence and in unambiguously identifying all the membrane-spanning segments. More sophisticated computer algorithms have been developed that take into account the presence of positively charged amino acids adjacent to hydrophobic segments as well as the length of and spacing between segments. Using all this information, the best algorithms can predict the complex topology of multipass proteins with an accuracy of greater than 80 percent.

Finally, sequence homology to a known protein may permit accurate prediction of the topology of a newly discovered multipass protein. For example, the genomes of multicellular organisms encode a very large number of multipass proteins with seven hydrophobic transmembrane segments. The similarities between the sequences of these proteins strongly suggest that all have the same topology as the well-studied G protein–coupled receptors, which have the N-terminus oriented to the exoplasmic side and the C-terminus oriented to the cytosolic side of the membrane.

KEY CONCEPTS OF SECTION 13.2

Insertion of Membrane Proteins into the ER

- Proteins synthesized on the rough ER include five topological classes of integral membrane proteins as well as a lipid-anchored type protein (see Figure 13-10).
- Topogenic sequences — N-terminal signal sequences, internal stop-transfer anchor sequences, and internal signal-anchor sequences — direct the insertion of nascent proteins into the ER membrane and their orientation within it. This orientation is retained during transport of the completed membrane protein to its final destination — for example, the plasma membrane.
- Single-pass membrane proteins that are initiated by interaction with SRP and are synthesized on ribosomes bound to the translocon are of three topological varieties: type I, type II, and type III. The topological type depends on the presence or absence of a signal sequence, the length of the hydrophilic N-terminal segment, and the arrangement of positively charged residues adjacent to the hydrophobic transmembrane segment (see Figure 13-14).
- Tail-anchored proteins that have a single C-terminal transmembrane domain are inserted into the membrane post-translationally. Their insertion depends on a cytosolic receptor, Get3, which is an ATPase with similarity to the GTPase domains of SRP and SRP receptor.
- The topology of multipass (type IV) proteins is established by the orientation of the first transmembrane segment according to the same principles as for single-pass proteins. Each additional transmembrane segment engages the translocon in sequential order as they emerge from the ribosome and thus are inserted in the membrane in alternating orientation.
- Some cell-surface proteins are initially synthesized as type I proteins, but then cleaved, and their luminal domains transferred to a GPI anchor (see Figure 13-15).
- The topology of membrane proteins can often be correctly predicted by computer programs that identify hydrophobic topogenic segments within the amino acid sequence and generate hydropathy profiles (see Figure 13-16).

13.3 Protein Modifications, Folding, and Quality Control in the ER

Membrane and soluble secretory proteins synthesized on the rough ER undergo four principal modifications before they reach their final destinations: (1) covalent addition and processing of carbohydrates (*glycosylation*) in the ER and Golgi complex; (2) formation of disulfide bonds in the ER; (3) proper folding of polypeptide chains and assembly of multisubunit proteins in the ER; and (4) specific proteolytic cleavages in the ER, Golgi complex, and secretory vesicles. Generally speaking, these modifications promote the folding of secretory proteins into their native structures and add structural stability to proteins exposed to the extracellular environment. Modifications such as glycosylation also allow the cell to produce a vast array of chemically distinct molecules at the cell surface that are the basis of specific molecular interactions used in cell-to-cell adhesion and communication.

The majority of proteins that are synthesized on the rough ER and enter the lumen of the ER are modified by the addition of one or more carbohydrate chains. Proteins with attached carbohydrates are known as **glycoproteins**. Carbohydrate chains in glycoproteins attached to the hydroxyl (—OH) group in serine and threonine residues are referred to as ***O*-linked oligosaccharides**, and carbohydrate chains attached to the amide nitrogen of asparagine are referred to as ***N*-linked oligosaccharides**. The various types of *O*-

linked oligosaccharides include the mucin-type *O*-linked chains (named after the abundant glycoproteins found in mucus) and the carbohydrate modifications on proteoglycans described in Chapter 20. *O*-linked chains typically consist of sugar residues in a linear chain, which are added to proteins by enzymes known as *glycoslytransferases*, located in the lumen of the Golgi complex. The more common *N*-linked oligosaccharides have a branched structure and are initially added to proteins in the ER. In this section, we focus on *N*-linked oligosaccharides, which are synthesized as a branched precursor in the ER. After the initial transfer of *N*-linked precursor to a protein in the ER, the oligosaccharide chain is modified in the ER and commonly in the Golgi complex as well.

Disulfide bond formation, protein folding, and assembly of multimeric proteins, which take place exclusively in the rough ER, are also discussed in this section. Only properly folded and assembled proteins are transported from the rough ER to the Golgi complex and ultimately to the cell surface or other final destination through the secretory pathway. Unfolded, misfolded, or partly folded and assembled proteins are selectively retained in the rough ER and marked for degradation. We consider several features of such quality control in the latter part of this section.

As discussed previously, N-terminal ER signal sequences are cleaved from soluble secretory proteins and type I membrane proteins in the ER. Some proteins also undergo other specific proteolytic

cleavages in the Golgi complex or secretory vesicles. We cover these cleavages, as well as carbohydrate modifications that occur primarily or exclusively in the Golgi complex, in the next chapter.

A Preformed *N*-Linked Oligosaccharide Is Added to Many Proteins in the Rough ER

Biosynthesis of all *N*-linked oligosaccharides begins in the rough ER with a preformed oligosaccharide precursor containing 14 residues (Figure 13-17). The structure of this precursor is the same in plants, animals, and single-celled eukaryotes: a branched oligosaccharide, containing three glucose (Glc), nine mannose (Man), and two *N*-acetylglucosamine (GlcNAc) molecules, which can be written as $Glc_3Man_9(GlcNAc)_2$. Once added to a protein, this branched carbohydrate structure is modified by addition or removal of monosaccharides in the ER and Golgi complex. The modifications to *N*-linked chains differ from one glycoprotein to another and among different organisms, but a core of 5 of the 14 residues is conserved in the structures of all *N*-linked oligosaccharides on secretory and membrane proteins.

FIGURE 13-17 Biosynthesis of the oligosaccharide precursor. Dolichol phosphate is a strongly hydrophobic lipid, containing 75–95 carbon atoms, that is embedded in the ER membrane. Two *N*-acetylglucosamine (GlcNAc) and five mannose residues are added one at a time to a dolichol phosphate on the cytosolic face of the ER membrane (steps **1**–**3**). The nucleotide-sugar donors in these and later reactions are synthesized in the cytosol. Note that the first sugar residue is attached to dolichol by a high-energy pyrophosphate linkage. Tunicamycin, which blocks the first enzyme in this pathway, inhibits the synthesis of all *N*-linked oligosaccharides in cells. After the seven-residue dolichol pyrophosphoryl intermediate is flipped to the luminal face (step **4**), the remaining four mannose residues and all three glucose residues are added one at a time (steps **5**–**6**). In the later reactions, the sugar to be added is first transferred from a nucleotide sugar to a carrier dolichol phosphate on the cytosolic face of the ER; the carrier is then flipped to the luminal face, where the sugar is transferred to the growing oligosaccharide, after which the "empty" carrier is flipped back to the cytosolic face. See C. Abeijon and C. B. Hirschberg, 1992, *Trends Biochem. Sci.* **17**:32.

Prior to transfer to a nascent chain in the lumen of the ER, the oligosaccharide precursor is assembled on a membrane-attached anchor called **dolichol phosphate**, a long-chain polyisoprenoid lipid (see Chapter 10). After the first sugar, GlcNAc, is attached to the dolichol phosphate by a pyrophosphate bond, the other sugars are added by glycosidic bonds in a complex set of reactions catalyzed by

enzymes attached to the cytosolic or luminal faces of the rough ER membrane (see Figure 13-17). The final dolichol pyrophosphoryl oligosaccharide is oriented so that the oligosaccharide portion faces the ER lumen. The three glucose residues, which are the last residues added during synthesis of the precursor on the dolichol carrier, appear to act as a signal that the oligosaccharide is complete and ready to be transferred to a protein.

The entire 14-residue precursor is transferred from the dolichol carrier to an asparagine residue on a nascent polypeptide as it emerges into the ER lumen (Figure 13-18, step **1**). Only asparagine residues in the tripeptide sequences Asn-X-Ser and Asn-X-Thr (where X is any amino acid except proline) are substrates for *oligosaccharyl transferase*, the enzyme that catalyzes this reaction. Two of the three subunits of this enzyme are ER membrane proteins whose cytosol-facing domains bind to the ribosome, localizing a third subunit of the transferase, the catalytic subunit, near the growing polypeptide chain in the ER lumen. Not all Asn-X-Ser/Thr sequences become glycosylated, and it is not possible to predict from the amino acid sequence alone which potential *N*-linked glycosylation sites will be modified; for instance, rapid folding of a segment of a protein containing an Asn-X-Ser/Thr sequence may prevent transfer of the oligosaccharide precursor to it. Immediately after the entire precursor, $Glc_3Man_9(GlcNAc)_2$, is transferred to a nascent polypeptide, three different enzymes, called *glycosidases*,

remove all three glucose residues and one particular mannose residue (see Figure 13-18, steps 2 – 4).

FIGURE 13-18 Addition and initial processing of *N*-linked oligosaccharides. In the rough ER of vertebrate cells, the $Glc_3Man_9(GlcNAc)_2$ precursor is transferred from the dolichol carrier to a susceptible asparagine residue on a nascent protein as soon as the asparagine crosses to the luminal side of the ER (step 1). In three separate reactions, first one glucose residue (step 2), then two glucose residues (steps 3a and 3b), and finally one mannose residue (step 4) are removed. Re-addition of one glucose residue (step 3c) plays a role in the correct folding of many proteins in the ER, as discussed later. The process of *N*-linked glycosylation of a soluble secretory protein is shown here, but the luminal portions of an integral membrane protein can be modified on asparagine residues by the same mechanism. See R. Kornfeld and S. Kornfeld, 1985, *Annu. Rev. Biochem.* **45**:631; and M. Sousa and A. J. Parodi, 1995, *EMBO J.* **14**:4196.

Oligosaccharide Side Chains May Promote Folding and Stability of Glycoproteins

The oligosaccharides attached to glycoproteins serve various functions. For example, some proteins require *N*-linked oligosaccharides in order to fold properly in the ER. This function has been demonstrated in studies with the antibiotic tunicamycin, which blocks the first step in the formation of the dolichol-linked oligosaccharide precursor and therefore inhibits synthesis of all *N*-linked oligosaccharides in cells (see Figure 13-17, *top left*). For example, in the presence of tunicamycin, the influenza virus hemagglutinin precursor polypeptide (HA_0) is synthesized, but it cannot fold properly and form a normal trimer; in this case, the misfolded protein remains in the rough ER. Moreover, mutation of a particular asparagine in the hemagglutinin sequence to a glutamine residue prevents addition of an *N*-linked oligosaccharide to that site and causes the protein to accumulate in the ER in an unfolded state.

In addition to promoting proper folding, *N*-linked oligosaccharides confer stability on many secreted glycoproteins. Many secretory proteins fold properly and are transported to their final destination even if the addition of all *N*-linked oligosaccharides is blocked, for example, by treatment with tunicamycin. However, such nonglycosylated proteins have been shown to be less stable than their glycosylated forms. For instance, glycosylated fibronectin, a normal component of the extracellular matrix, is degraded much more slowly by tissue proteases than is nonglycosylated fibronectin.

Oligosaccharides on certain cell-surface glycoproteins also play a role in cell-cell adhesion. For example, the plasma membrane of white blood cells (leukocytes) contains cell-adhesion molecules (CAMs) that are extensively glycosylated. The oligosaccharides in these molecules interact with a sugar-binding domain in certain other CAMs found on endothelial cells lining blood vessels. This interaction tethers the leukocytes to the endothelium and assists in their movement into tissues during an inflammatory response to infection (see Figure 20-40). Other cell-surface glycoproteins possess oligosaccharide side chains that can induce an immune response. A common example is the ABO blood group antigens, which are *O*-linked oligosaccharides attached to glycoproteins and glycolipids on the surfaces of erythrocytes and other cell types (see Figure 10-20). In both cases, oligosaccharides are added to the luminal face of these membrane proteins, in a manner similar to what is shown in Figure 13-18 for soluble proteins. The luminal face of these membrane proteins is topologically equivalent to the exterior face of the plasma membrane, where these proteins eventually end up.

Disulfide Bonds Are Formed and Rearranged by Proteins in the ER Lumen

In Chapter 3, we learned that both intramolecular and intermolecular **disulfide bonds** (**–S–S–**) help stabilize the tertiary

and quaternary structure of many proteins. These covalent bonds form by the oxidative linkage of *sulfhydryl groups (–SH)*, also known as *thiol* groups, on two cysteine residues in the same or different polypeptide chains. This reaction can proceed only when a suitable oxidant is present. In eukaryotic cells, disulfide bonds are formed in the lumen of the rough ER and are typically found in soluble secretory proteins and in the exoplasmic domains of membrane proteins. The cytosol does not contain enzymes for disulfide bond formation and therefore cytosolic proteins and most organelle proteins (i.e., those destined for mitochondria, chloroplasts, peroxisomes, etc.) usually lack disulfide bonds.

The efficient formation of disulfide bonds in the lumen of the ER depends on the enzyme **protein disulfide isomerase (PDI)**, which is present in all eukaryotic cells. This enzyme is especially abundant in the ER of secretory cells in organs such as the liver and pancreas, where large quantities of proteins that contain disulfide bonds are produced. As shown in Figure 13-19a, the disulfide bond in the active site of PDI can be readily transferred to a protein by two sequential thiol-disulfide transfer reactions. The reduced PDI generated by this reaction is returned to an oxidized form by the action of an ER-resident protein, called *Ero1*, which carries a disulfide bond that can be transferred to PDI. Ero1 itself becomes oxidized by reaction with molecular oxygen that has diffused into the ER.

FIGURE 13-19 Action of protein disulfide isomerase (PDI). PDI forms and rearranges disulfide bonds via an active site with two closely spaced cysteine residues that are easily interconverted between the reduced dithiol form and the oxidized disulfide form. Numbered red arrows indicate the sequence of electron transfers. Yellow bars represent disulfide bonds. (a) In the formation of disulfide bonds, the ionized ($-S^-$) form of a cysteine thiol in the substrate protein reacts with the disulfide (S–S) bond in oxidized PDI to form a disulfide-bonded PDI–substrate protein intermediate. A second ionized thiol in the substrate protein then reacts with this intermediate, forming a disulfide bond within the substrate protein and releasing reduced PDI. PDI, in turn, transfers electrons to a disulfide bond in the luminal protein Ero1, thereby regenerating the oxidized form of PDI. (b) Reduced PDI can catalyze rearrangement of improperly formed disulfide bonds by similar thiol-disulfide transfer reactions. In this case, reduced PDI both initiates and is regenerated in the reaction pathway. These reactions are repeated until the most stable conformation of the protein is achieved. See M. M. Lyles and H. F. Gilbert, 1991, *Biochemistry* **30**:619.

In proteins that contain more than one disulfide bond, the proper pairing of cysteine residues is essential for normal structure and activity. Disulfide bonds are commonly formed between cysteines that occur sequentially in the amino acid sequence while a polypeptide is still growing on the ribosome. Such sequential formation, however, sometimes yields disulfide bonds between the wrong cysteines. For example, proinsulin, a precursor to the peptide hormone insulin, has three disulfide bonds that link cysteines 1 and 4, 2 and 6, and 3 and 5. In this case, a disulfide bond that initially formed sequentially (e.g., between cysteines 1 and 2) would have to be rearranged for the protein to achieve its proper folded conformation. In cells, the rearrangement of disulfide bonds is also accelerated by PDI, which acts on a broad range of protein substrates, allowing them to reach their most thermodynamically stable conformations (Figure 13-19b). Disulfide bonds generally form in a specific order, first stabilizing small domains of a polypeptide, then stabilizing the interactions of more distant segments; this phenomenon is illustrated by the folding of the influenza hemagglutinin (HA) protein, discussed in the next section.

Chaperones and Other ER Proteins Facilitate Folding and Assembly of Proteins

Although many denatured proteins can spontaneously refold into their native state in vitro, such refolding usually requires hours to reach completion. Yet proteins produced in the ER generally fold into their proper conformation within minutes after their synthesis. The rapid folding of these newly synthesized proteins in cells depends on the sequential action of several proteins present within the ER lumen. We have already seen how the molecular chaperone BiP can drive post-translational translocation in yeast by binding fully synthesized polypeptides as they enter the ER (see Figure 13-9). BiP can also bind transiently to nascent polypeptide chains as they enter the ER during cotranslational translocation. Bound BiP is thought to prevent segments of a nascent chain from misfolding or forming aggregates, thereby promoting folding of the entire polypeptide into the proper conformation. PDI also contributes to proper folding because the correct three-dimensional conformation is stabilized by disulfide bonds in many proteins.

As illustrated in Figure 13-20, two other ER proteins, the homologous lectins (carbohydrate-binding proteins) *calnexin* and *calreticulin*, bind selectively to certain *N*-linked oligosaccharides on growing polypeptide chains. The ligand for these two proteins, which resembles the *N*-linked oligosaccharide precursor but has only a single glucose residue $[Glc_1Man_9(GlcNAc)_2]$, is generated by a specific glucosyltransferase in the ER lumen (see Figure 13-18, step **3a**). This enzyme acts only on polypeptide chains that are unfolded or misfolded, and in this respect, the glucosyltransferase acts as one

of the primary surveillance mechanisms to ensure quality control of protein folding in the ER. Unfolded proteins often expose hydrophobic segments that in a properly folded state are buried in the hydrophobic core of the protein. The glucosyltransferase is thought to specifically recognize unfolded proteins by binding to these exposed hydrophobic segments. Binding of calnexin and calreticulin to unfolded nascent chains marked with glucosylated *N*-linked oligosaccharides prevents aggregation of adjacent segments of a protein as it is being made on the ER. Thus calnexin and calreticulin, like BiP, help prevent premature, incorrect folding of segments of a newly made protein.

FIGURE 13-20 Hemagglutinin folding and assembly. (a) Mechanism of (HA_0) trimer assembly. Transient binding of the chaperone BiP (step **1a**) to the nascent polypeptide chain and of two lectins, calnexin and calreticulin, to certain oligosaccharide chains (step **1b**) promotes proper folding of adjacent segments of HA_0. A total of seven *N*-linked oligosaccharide chains are added to the luminal portion of the nascent chain during cotranslational translocation, and PDI catalyzes the formation of six disulfide bonds per monomer. Completed HA_0 monomers are anchored in the membrane by a single membrane-spanning α helix with the N-terminus in the lumen (step **2**). Interaction of three HA_0 chains with one another, initially via their transmembrane α helices, apparently triggers formation of a long stem containing one α helix from the luminal part of each HA_0 polypeptide. Finally, interactions occur among the three globular heads, generating a stable HA_0 trimer (step **3**). (b) Electron micrograph (false color) of a complete influenza virion

showing trimers of HA protein protruding as spikes from the surface of the viral membrane. See U. Tatu et al., 1995, *EMBO J.* **14**:1340; and D. Hebert et al., 1997, *J. Cell Biol.* **139**:613.

Other important protein-folding catalysts in the ER lumen are *peptidyl-prolyl isomerases*, a family of enzymes that accelerate the rotation about peptidyl-prolyl bonds at proline residues in unfolded segments of a polypeptide:

Such isomerizations are sometimes the rate-limiting step in the folding of protein domains. Many peptidyl-prolyl isomerases can catalyze the rotation of exposed peptidyl-prolyl bonds indiscriminately in numerous proteins, but some have very specific protein substrates.

Many important soluble secretory and membrane proteins synthesized on the ER are built of two or more polypeptide subunits. In all cases, the assembly of the subunits constituting these multisubunit (multimeric) proteins occurs in the ER. The

immunoglobulins, which contain two heavy (H) and two light (L) chains, all linked by intrachain disulfide bonds, are assembled in this way. Hemagglutinin (HA) is another multimeric protein that provides a good illustration of folding and subunit assembly (see Figure 13-20). This trimeric protein forms the spikes that protrude from the surface of an influenza virus particle. The HA trimer is formed within the ER of an infected host cell from three copies of a precursor protein termed HA_0, which has a single membrane-spanning α helix. In the Golgi complex, each of the three HA_0 proteins is cleaved to form two polypeptides, HA_1 and HA_2; thus each HA molecule that eventually resides on the viral surface contains three copies of HA_1 and three of HA_2 (see Figure 3-10). The trimer is stabilized by interactions between the large exoplasmic domains of the constituent polypeptides, which extend into the ER lumen; after HA is transported to the cell surface, these domains extend into the extracellular space. Interactions between the smaller cytosolic and membrane-spanning portions of the HA subunits also help stabilize the trimeric protein. Studies have shown that it takes just 10 minutes for the HA_0 polypeptides to fold and assemble into their proper trimeric conformation.

Improperly Folded Proteins in the ER Induce Expression of Protein-Folding Catalysts

Wild-type proteins that are synthesized on the rough ER cannot exit this compartment until they achieve their completely folded conformation. Likewise, almost any mutation that prevents proper folding of a protein in the ER also blocks the movement of that protein from the ER lumen or membrane to the Golgi complex. The mechanisms that retain unfolded or incompletely folded proteins within the ER probably increase the overall efficiency of folding by keeping intermediate forms in proximity to folding catalysts, which are most abundant in the ER. Improperly folded proteins retained within the ER are generally seen bound to the ER chaperones BiP and calnexin. Thus these luminal folding catalysts perform two related functions: assisting in the folding of normal proteins by preventing their aggregation and binding to misfolded proteins to retain them in the ER.

Both mammalian cells and yeasts respond to the presence of unfolded proteins in the rough ER by increasing transcription of several genes that encode ER chaperones and other folding catalysts. A key participant in this **unfolded-protein response** is Ire1, an ER membrane protein that exists both as a monomer and as a dimer. The dimeric form, but not the monomeric form, promotes formation of Hac1, a transcription factor in yeast that activates expression of the genes induced in the unfolded-protein response. As depicted in Figure 13-21, binding of BiP to the luminal domain of monomeric Ire1 prevents formation of the Ire1 dimer. Thus the quantity of free BiP in the ER lumen determines the relative proportions of monomeric and dimeric Ire1. Accumulation of

unfolded proteins within the ER lumen sequesters BiP molecules, making them unavailable for binding to Ire1. As a result, the level of dimeric Ire1 increases, leading to an increase in the level of Hac1 and production of proteins that assist in protein folding.

FIGURE 13-21 The unfolded-protein response. Ire1, a transmembrane protein in the ER membrane, has a binding site for BiP on its luminal domain; the cytosolic domain contains a specific RNA endonuclease. Step 1: Accumulating unfolded proteins in the ER lumen bind BiP molecules, releasing them from monomeric Ire1. Dimerization of Ire1 then activates its

endonuclease activity. Steps 2 – 3 : The unspliced mRNA precursor encoding the transcription factor Hac1 is cleaved by dimeric Ire1, and the two exons are joined to form functional Hac1 mRNA. Current evidence indicates that this processing occurs in the cytosol, although pre-mRNA processing generally occurs in the nucleus. Step 4 : Hac1 is translated into Hac1 protein, which then moves back into the nucleus and activates transcription of genes encoding several protein-folding catalysts. See U. Ruegsegger et al., 2001, *Cell* **107**:103; A. Bertolotti et al., 2000, *Nat. Cell Biol.* **2**:326; and C. Sidrauski and P. Walter, 1997, *Cell* **90**:1031.

Mammalian cells contain an additional regulatory pathway that operates in response to unfolded proteins in the ER. In this pathway, accumulation of unfolded proteins in the ER triggers proteolysis of ATF6, a transmembrane protein in the ER membrane, at a site within the membrane-spanning segment. The cytosolic domain of ATF6 released by proteolysis then moves to the nucleus, where it stimulates transcription of the genes encoding ER chaperones. Activation of a transcription factor by such *regulated intramembrane proteolysis* also occurs in the Notch signaling pathway and during activation of the cholesterol-responsive transcription factor SREBP (see Figures 16-25 and 21-6).

A hereditary form of emphysema illustrates the detrimental effects that can result from misfolding of proteins in the ER. This disease is caused by a point mutation in α_1-antitrypsin, which is normally secreted by hepatocytes and macrophages. The wild-type protein binds to and inhibits trypsin as well as the blood protease elastase. In the absence of normal α_1-antitrypsin, elastase degrades

the fine tissue in the lung that participates in the absorption of oxygen, eventually producing the symptoms of emphysema. Although the mutant α_1-antitrypsin is synthesized on the rough ER, it does not fold properly, forming an almost crystalline aggregate that is not exported from the ER. In hepatocytes, the secretion of other proteins also becomes impaired as the rough ER is filled with aggregated α_1-antitrypsin. ■

Unassembled or Misfolded Proteins in the ER Are Often Transported to the Cytosol for Degradation

Misfolded soluble secretory and membrane proteins, as well as the unassembled subunits of multimeric proteins, are often degraded within an hour or two after their synthesis in the rough ER. Initially, it was thought that proteolytic enzymes within the ER lumen catalyzed degradation of misfolded or unassembled polypeptides, but such proteases were never found. More recent studies have shown that misfolded secretory proteins are recognized by specific ER membrane proteins and are targeted for transport from the ER lumen into the cytosol by a process known as **dislocation**.

The dislocation and degradation of misfolded proteins depends on a set of proteins located in the ER membrane and in the cytosol that perform three basic functions. The first function is recognition of

misfolded proteins. One mechanism for recognition involves the trimming of *N*-linked carbohydrate chains by mannosidases located in the ER (Figure 13-22). Trimmed glycans with the structure $\mathrm{Man}_{5\text{–}6}(\mathrm{GlcNAc})_2$ are recognized by a protein known as *OS-9*, which targets the trimmed glycoprotein for dislocation. It is not known precisely how the ER α-mannosidases distinguish the partially folded states of defective proteins that can never completely fold properly and are thus legitimate substrates for the dislocation process, from normal proteins that have not yet acquired their fully folded conformation. One possibility is that the ER α-mannosidases act slowly, so that only those glycoproteins that remain misfolded in the ER lumen for a sufficiently long time are trimmed and therefore targeted for degradation. Luminal proteins that lack oligosaccharides altogether can also be targeted for degradation, indicating that other processes for the recognition of unfolded proteins must also exist that do not involve trimming of *N*-linked oligosaccharides.

FIGURE 13-22 Modifications of *N*-linked oligosaccharides are used to monitor folding and for quality control. After a $\mathrm{Glc}_3\mathrm{Man}_9(\mathrm{GlcNAc})_2$ *N*-linked oligosaccharide is added to a

newly synthesized and incompletely folded protein in the ER, three glucose residues are removed by Glucosidases I and II to form $\mathrm{Glc_1Man_9(GlcNAc)_2}$ (see Figure 13-18, steps 2 and 3). This modified *N*-linked oligosaccharide binds the lectins calnexin (CNX) and calreticulin (CRT) for retention in the ER and engagement of folding chaperones. When the *N*-linked oligosaccharide is released from $\mathrm{CNX/and}$ CRT, removal of glucose by Glucosidase II yields $\mathrm{Man_9(GlcNAc)_2}$, which is further processed to $\mathrm{Man_8(GlcNAc)_2}$ before entering a COPII vesicle bound for the *cis*-Golgi (see Figure 13-18, steps 3 and 4). If the protein has not folded completely, a glucosyltransferase known as *UGGT* can add a glucose residue to reform $\mathrm{Glc_1Man_9(GlcNAc)_2}$, which will bind again to CNX and CRT for another attempt at folding. Proteins that cannot fold properly, and are therefore retained in the ER for longer times, eventually undergo mannose trimming by ER α-mannosidases to form $\mathrm{Man_{5\text{–}6}(GlcNAc)_2}$, which is recognized by OS-9. Recognition by OS-9 leads to dislocation of the misfolded protein out of the ER, ubiquitinylation, and degradation by proteasomes.

Misfolded ER proteins that are marked for degradation are transported across the ER membrane by a process known as *dislocation*, since it occurs in the reverse direction from translocation, which occurs during synthesis. A complex of at least four integral membrane proteins, known as the **ERAD (*ER-associated degradation*)** complex, enables dislocation of misfolded proteins across the ER membrane, but there is no evidence that the ERAD complex forms a protein channel for dislocation, suggesting other possible mechanisms. One possibility is that the Sec61 translocation channel can be repurposed for the dislocation of misfolded proteins from the ER lumen to the cytosol. Dislocation involves powerful pulling and unfolding protein machines in the cytosol and it is possible that misfolded proteins are dragged directly through the lipid bilayer without a channel dedicated for this purpose.

As segments of a dislocated polypeptide emerge on the cytosolic face of the membrane, they encounter p97, a member of a protein family known as the **AAA ATPase family** that couples the energy of ATP hydrolysis to disassembly of protein complexes. In dislocation of polypeptides from the ER, hydrolysis of ATP by p97 may provide the driving force to pull misfolded proteins from the ER membrane into the cytosol. As the misfolded proteins enter the cytosol, specific ubiquitin ligase enzymes that are components of the ERAD complex add ubiquitin residues to these dislocated peptides. Like the action of p97, ubiquitinylation is coupled to ATP hydrolysis and this reaction may also contribute to the energetically favorable trapping of the proteins in the cytosol. The resulting polyubiquitinylated polypeptides, now fully in the cytosol, are targeted for degradation in proteasomes. The role of polyubiquitinylation in targeting proteins to proteasomes is discussed more fully in Chapter 3 (see Figure 3-32 and Figure 3-39).

KEY CONCEPTS OF SECTION 13.3

Protein Modifications, Folding, and Quality Control in the ER

- All *N*-linked oligosaccharides, which are bound to asparagine residues, contain a core of two *N*-acetylglucosamine and at least three mannose residues and usually have several branches. *O*-linked oligosaccharides, which are bound to serine or threonine residues, are generally short, often containing only one to four sugar residues.
- Formation of *N*-linked oligosaccharides begins with assembly of a conserved 14-residue high-mannose oligosaccharide precursor on dolichol, a lipid in the membrane of the rough ER (see Figure 13-17). After this preformed oligosaccharide is transferred

to specific asparagine residues of nascent polypeptide chains in the ER lumen, three glucose residues and one mannose residue are removed (see Figure 13-18).

- Oligosaccharide side chains may assist in the proper folding of glycoproteins, help protect the mature proteins from proteolysis, participate in cell-cell adhesion, and function as antigens.
- Disulfide bonds are added to many soluble secretory proteins and to the exoplasmic domain of membrane proteins in the ER. Protein disulfide isomerase (PDI), present in the ER lumen, catalyzes both the formation and the rearrangement of disulfide bonds (see Figure 13-19).
- The chaperone BiP, the lectins calnexin and calreticulin, and peptidyl-prolyl isomerases work together to ensure proper folding of newly made secretory and membrane proteins in the ER. The subunits of multimeric proteins also assemble in the ER (see Figure 13-20).
- Only properly folded proteins and assembled subunits are transported from the rough ER to the Golgi complex in vesicles.
- The accumulation of abnormally folded proteins and unassembled subunits in the ER can induce increased expression of ER protein-folding catalysts via the unfolded-protein response (see Figure 13-21).
- Unassembled or misfolded proteins in the ER are often transported back to the cytosol, where they are degraded in the ubiquitin-proteasome pathway (see Figure 13-22).

13.4 Targeting of Proteins to Mitochondria and Chloroplasts

In the remainder of this chapter, we examine how proteins synthesized on cytosolic ribosomes are sorted to discrete organelles: mitochondria, chloroplasts, peroxisomes, and the nucleus (see Figure 13-1). Mitochondria and chloroplasts are closely related organelles that contain an internal lumen — called the *matrix* in mitochondria and the *stroma* in chloroplasts — that is surrounded by a double membrane. Within the stroma, chloroplasts contain a third membrane known as the *thylakoid*, which is where the light-harvesting reactions of photosynthesis take place. In contrast to mitochondria and chloroplasts, peroxisomes are bounded by a single membrane and have a single luminal matrix compartment. The mechanism of protein transport into and out of the nucleus, which differs in many respects from sorting to other organelles, is discussed in the last section of the chapter.

In addition to being bounded by two membranes, mitochondria and chloroplasts share similar types of electron-transporting proteins and use an F-class ATPase to synthesize ATP (see Figure 12-26). Remarkably, these characteristics are shared by gram-negative bacteria. Also like bacterial cells, mitochondria and chloroplasts contain their own DNA, which encodes organelle rRNAs, tRNAs, and some proteins (see Chapter 8). Moreover, growth and division of mitochondria and chloroplasts are not coupled to nuclear division.

Rather, these organelles grow by the incorporation of cellular proteins and lipids, and new organelles form by division of preexisting organelles. These numerous similarities to free-living bacterial cells have led to the understanding that mitochondria and chloroplasts arose when bacteria were incorporated into ancestral eukaryotic cells, forming endosymbiotic organelles (see Figure 12-7). The sequence similarity of the many membrane translocation proteins shared by mitochondria, chloroplasts, and bacteria provides the most striking evidence for this ancient evolutionary relationship. In this section, we examine these membrane translocation proteins in detail.

Proteins encoded by mitochondrial DNA or chloroplast DNA are synthesized on ribosomes within the organelles and directed to the correct subcompartment within the parent organelle immediately after synthesis. However, the majority of proteins located in mitochondria and chloroplasts are not encoded by organelle DNA — they are encoded by genes in the nucleus and are imported into the organelles after their synthesis in the cytosol. Apparently, as eukaryotic cells evolved over a billion years, much of the genetic information from the ancestral bacterial DNA in these endosymbiotic organelles moved, by an unknown mechanism, to the nucleus. Precursor proteins synthesized in the cytosol that are destined for the matrix of mitochondria or the equivalent stroma in chloroplasts usually contain specific N-terminal targeting sequences that specify binding to receptor proteins on the organelle surface. Generally these sequences are cleaved once the protein reaches the

matrix or stroma. Clearly these targeting sequences are similar in their location and general function to the signal sequences that direct nascent proteins to the ER lumen. Although the three types of signals share some sequence features, their specific sequences differ considerably, as summarized in Table 13-1.

In both mitochondria and chloroplasts, protein import requires energy and occurs at points where the outer and inner organelle membranes are in direct contact. Because mitochondria and chloroplasts contain multiple membranes and membrane-limited spaces, the sorting of many proteins to their correct locations requires the sequential action of two targeting sequences and two membrane-bound translocation systems: one to direct the protein into the organelle and the other to direct it into the correct organelle subcompartment or membrane. As we will see, the mechanisms for sorting various proteins to mitochondria and chloroplasts are related to SRP-dependent recognition of a signal sequence as discussed previously.

Amphipathic N-Terminal Targeting Sequences Direct Proteins to the Mitochondrial Matrix

All proteins that travel from the cytosol to the same mitochondrial destination have targeting signals that share common motifs,

although the signal sequences are not identical. Thus the receptors that recognize such signals are able to bind to a number of different but related sequences. The most extensively studied sequences for localizing proteins to mitochondria are the *matrix-targeting sequences*. These sequences, located at the N-terminus, are usually 20–50 amino acids in length. They are rich in hydrophobic amino acids, positively charged basic amino acids (arginine and lysine), and hydroxylated ones (serine and threonine) but tend to lack negatively charged acidic residues (aspartate and glutamate).

Mitochondrial matrix–targeting sequences are thought to assume an α-helical conformation in which positively charged amino acids predominate on one side of the helix and hydrophobic amino acids on the other. Sequences such as these that contain both hydrophobic and hydrophilic regions are said to be amphipathic. Mutations that disrupt the amphipathic character of these sequences usually disrupt targeting to the matrix, although many other amino acid substitutions do not. These findings indicate that the amphipathicity of matrix-targeting sequences is critical to their function.

The cell-free assay outlined in Figure 13-23 has been widely used to define the biochemical steps in the import of mitochondrial precursor proteins. Respiring (energized) mitochondria extracted from cells can incorporate mitochondrial precursor proteins that have been synthesized in the absence of mitochondria if they are carrying appropriate targeting sequences. Successful incorporation

of the precursor into the organelle can be assayed by resistance to digestion by an added protease such as trypsin. In other assays, successful import of a precursor protein can be shown by the proper cleavage of the N-terminal targeting sequences by specific mitochondrial proteases. The uptake of completely presynthesized mitochondrial precursor proteins by the organelle in this system contrasts with the cell-free cotranslational translocation of secretory proteins into the ER, which generally occurs only when microsomal (ER-derived) membranes are present during synthesis (see Figure 13-4).

FIGURE 13-23 Import of mitochondrial precursor proteins is assayed in a cell-free system. Mitochondrial precursor proteins with attached uptake-targeting signals can be synthesized on ribosomes in a cell-free reaction. When respiring

mitochondria are added to these synthesized mitochondrial precursor proteins (*top*), the proteins are taken up by mitochondria. Inside mitochondria, the proteins are protected from the action of proteases such as trypsin. When no mitochondria are present (*bottom*), the mitochondrial proteins are degraded by added protease. Only energized (respiring) mitochondria, which have a proton electrochemical gradient (proton-motive force) across the inner membrane, take up these proteins. Furthermore, the imported proteins must contain an appropriate uptake-targeting sequence. Uptake also requires ATP and a cytosolic extract containing chaperone proteins that maintain the precursor proteins in an unfolded conformation. This assay has been used to study targeting sequences and other features of the translocation process.

Mitochondrial Protein Import Requires Outer-Membrane Receptors and Translocons in Both Membranes

Figure 13-24 presents an overview of protein import from the cytosol into the mitochondrial matrix, the route into the mitochondrion followed by most imported proteins. Here we discuss in detail each step of protein transport into the matrix, then consider how some proteins are subsequently targeted to other compartments of the mitochondrion.

FIGURE 13-24 Protein import into the mitochondrial matrix. Precursor proteins synthesized on cytosolic ribosomes are maintained in an unfolded or partially folded state by bound chaperones, such as cytosolic Hsp70 (step 1). After a precursor protein binds to an import receptor near a site of contact with the inner membrane (step 2), it is transferred into the general import pore (step 3). The translocating protein then moves through this channel and an adjacent channel in the inner membrane (steps 4–5). Note that

translocation occurs at rare “contact sites” at which the inner and outer membranes appear to touch. Binding of the translocating protein by matrix Hsp70 and subsequent ATP hydrolysis by Hsp70 helps drive import into the matrix. Once the targeting sequence is removed by a matrix protease and Hsp70 is released from the newly imported protein (step **6**), the protein folds into its mature, active conformation within the matrix (step **7**). Folding of some proteins depends on matrix chaperonins. See G. Schatz, 1996, *J. Biol. Chem.* **271**:31763; and N. Pfanner et al., 1997, *Annu. Rev. Cell Dev. Biol.* **13**:25.

After synthesis in the cytosol, the soluble precursors of mitochondrial proteins (including hydrophobic integral membrane proteins) can interact directly with the mitochondrial membrane. Import of an unfolded mitochondrial precursor protein is initiated by the binding of a mitochondrial targeting sequence to an *import receptor* in the outer mitochondrial membrane. These import receptors were first identified by experiments in which antibodies to specific proteins of the outer mitochondrial membrane were shown to inhibit protein import into isolated mitochondria. Subsequent genetic experiments in which the genes for specific mitochondrial outer-membrane proteins were mutated showed that specific receptor proteins were responsible for the import of different classes of mitochondrial proteins. For example, N-terminal matrix-targeting sequences are recognized by a complex of Tom20 and Tom22 (proteins in the outer mitochondrial membrane involved in targeting and import, designated *Tom* proteins for *t*ranslocon of the *o*uter *m*embrane).

Many proteins can be imported into the mitochondrion only in an unfolded state. Chaperone proteins such as cytosolic Hsp70 and Hsp90 use energy derived from ATP hydrolysis to keep nascent and newly made proteins in a disaggregated state so that they are available to be taken up by mitochondria. For some mitochondrial precursor proteins, the mitochondrial outer-membrane protein Tom70 serves as an import receptor by binding to both Hsp90 and portions of the unfolded precursor protein.

The import receptors subsequently transfer the precursor protein to an import channel in the outer membrane. This channel, composed mainly of the Tom40 protein, is known as the **general import pore** because all known mitochondrial precursor proteins gain access to the interior compartments of the mitochondrion through it. When Tom40 is purified and incorporated into liposomes, it forms a transmembrane channel with a pore wide enough to accommodate an unfolded polypeptide chain. The general import pore forms a largely passive channel through the outer mitochondrial membrane; the driving force for unidirectional transport comes from within the mitochondrion, as we will see shortly. In the case of precursors destined for the mitochondrial matrix, transfer through the outer membrane occurs simultaneously with transfer through an inner-membrane channel composed of the Tim23 and Tim17 proteins. (*Tim* stands for *t*ranslocon of the *i*nner *m*embrane.) Translocation into the matrix thus occurs at contact sites where the outer and inner membranes are in close proximity.

Soon after the N-terminal matrix-targeting sequence of a protein enters the mitochondrial matrix, it is removed by a protease that resides within the matrix. The emerging protein is also bound by matrix Hsp70, a chaperone that is localized to the translocation channels in the inner mitochondrial membrane by interaction with transmembrane protein Tim44. Together, Tim44 and Hsp70 are thought to power translocation of proteins into the matrix.

Some imported proteins can fold into their final, active conformation without further assistance. Final folding of many matrix proteins, however, requires chaperonins. As discussed in Chapter 3, chaperonin proteins actively facilitate protein folding by a process that depends on ATP. Yeast mutants defective in Hsc60, a chaperonin in the mitochondrial matrix, can import matrix proteins and cleave their targeting sequences normally, but the imported polypeptides fail to fold and assemble into their native tertiary and quaternary structures.

Studies with Chimeric Proteins Demonstrate Important Features of Mitochondrial Protein Import

Dramatic evidence for the ability of mitochondrial matrix–targeting sequences to direct the import of any protein to the matrix was shown by adding the matrix-targeting sequence of alcohol

dehydrogenase to the enzyme dihydrofolate reductase (DHFR), which normally resides in the cytosol. Cell-free translocation assays show that in the presence of chaperones, which prevent the DHFR segment from folding in the cytosol, the chimeric protein is transported into the matrix (Figure 13-25a). However, the DHFR inhibitor methotrexate, which binds tightly to the active site of DHFR and greatly stabilizes its folded conformation, renders the chimeric protein resistant to unfolding by cytosolic chaperones and prevents the chimeric protein from completely entering the translocon of the matrix. This finding demonstrates that a precursor must be unfolded in order to traverse the import pores in both mitochondrial membranes.

EXPERIMENTAL FIGURE 13-25 Experiments with chimeric proteins elucidate mitochondrial protein import processes. These experiments show that a matrix-targeting sequence alone directs proteins to the mitochondrial matrix and that only unfolded proteins are translocated across both mitochondrial membranes. The chimeric protein in these experiments contained a matrix-targeting signal at its N-terminus (red), followed by a spacer sequence of no particular function (black), and then by dihydrofolate reductase (DHFR), an

enzyme normally present only in the cytosol. (a) When the DHFR segment is unfolded, the chimeric protein moves across both membranes to the matrix of an energized mitochondrion, and the matrix-targeting signal is then removed. (b) When the C-terminus of the chimeric protein is locked in the folded state by binding of methotrexate, translocation is blocked. If the spacer sequence is long enough to extend across both transport channels, a stable translocation intermediate with the targeting sequence cleaved off is generated in the presence of methotrexate, as shown here. (c) The C-terminus of the translocation intermediate in (b) can be detected by incubating the mitochondria with antibodies that bind to the DHFR segment, followed by gold particles coated with bacterial protein A, which binds nonspecifically to antibody molecules (see Figure 4-33). An electron micrograph of a sectioned sample reveals gold particles (red arrowhead) bound to the translocation intermediate at a contact site between the inner and outer membranes. Other contact sites (black arrows) are also evident. See J. Rassow et al., 1990, *FEBS Lett.* **275**:190.

[Part (c) M. Schwaiger, V. Herzog, and W. Neupert, 1987, *J. Cell Biol*. **105**:235–246; https://doi.org/10.1083/jcb.105.1.235.]

Additional studies revealed that if a sufficiently long spacer sequence separates the N-terminal matrix-targeting sequence and the DHFR portion of the chimeric protein, then, in the presence of methotrexate, a translocation intermediate that spans both membranes can be trapped (Figure 13-25b). Microscopy studies of these stable trapped intermediates show that they accumulate at sites where the inner and outer mitochondrial membranes are close together (Figure 13-25c). Since roughly a thousand stuck chimeric proteins can be observed at these *contact sites* in a typical yeast mitochondrion, it is thought that mitochondria have approximately a thousand general import pores for the uptake of mitochondrial proteins.

Three Energy Inputs Are Needed to Import Proteins into Mitochondria

As noted previously and as indicated in Figure 13-24, ATP hydrolysis by Hsp70 chaperone proteins in both the cytosol and the mitochondrial matrix is required for the import of mitochondrial proteins. Cytosolic Hsp70 expends energy to maintain bound precursor proteins in an unfolded state so that they can be translocated into the matrix. The importance of ATP to this function was demonstrated in studies in which a mitochondrial precursor protein was purified and then denatured (unfolded) by urea. When tested in the cell-free mitochondrial translocation system, the denatured protein was incorporated into the matrix in the absence of ATP. In contrast, the same precursor protein in its native, undenatured state was not imported in the absence of ATP, even in the presence of cytosolic chaperones.

The sequential binding to and ATP-driven release of multiple matrix Hsp70 molecules from a translocating protein may simply trap the unfolded protein in the matrix. In this case, the functions of matrix Hsp70 and Tim44 would be analogous to those of the chaperone BiP and Sec63 complex, respectively, in post-translational translocation into the ER lumen (see Figure 13-9).

The third energy input required for mitochondrial protein import is an H^+ electrochemical gradient, or *proton-motive force*, across the

inner membrane. Recall from Chapter 12 that protons are pumped from the matrix into the intermembrane space during electron transport, creating an electric potential across the inner membrane. In general, only mitochondria that are actively undergoing respiration, and therefore have generated a proton-motive force across the inner membrane, are able to translocate precursor proteins from the cytosol into the mitochondrial matrix. Treatment of mitochondria with inhibitors or uncouplers of oxidative phosphorylation, such as cyanide or dinitrophenol, dissipates this proton-motive force. Although precursor proteins can still bind tightly to receptors on such poisoned mitochondria, the proteins cannot be imported, either in intact cells or in cell-free systems, even in the presence of ATP and chaperone proteins. Once a protein is partially inserted into the inner membrane, it is subjected to a membrane potential of 200 mV (matrix negative). This seemingly small potential is established across the very narrow hydrophobic core of the lipid bilayer, which gives an enormous electrochemical gradient, equivalent to about 400,000 V/cm. The positive charges in the amphipathic matrix-targeting sequence may simply be pulled into the matrix by the inside-negative membrane potential.

Multiple Signals and Pathways Target Proteins to Submitochondrial Compartments

Unlike targeting to the matrix, targeting of proteins to the intermembrane space, inner membrane, or outer membrane of mitochondria generally requires more than one targeting sequence and occurs via one of several pathways. Figure 13-26 summarizes the organization of targeting sequences in proteins sorted to different mitochondrial locations.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 13-26 Targeting sequences in imported mitochondrial proteins. Most mitochondrial proteins have an N-terminal matrix-targeting sequence (pink) that is similar, though not identical, in different proteins. Proteins destined for

the inner membrane, the intermembrane space, or the outer membrane have one or more additional targeting sequences that function to direct the proteins to these locations by several different pathways. The lettered pathways correspond to those illustrated in Figures 13-27 and 13-28. See W. Neupert, 1997, *Annu. Rev. Biochem.* **66**:863.

Inner-Membrane Proteins

Three separate pathways are known to target proteins to the inner mitochondrial membrane. One pathway makes use of the same machinery that is used for the targeting of matrix proteins (Figure 13-27, path A). A cytochrome oxidase subunit called *CoxVa* is one protein transported by this pathway. The precursor form of CoxVa, which contains an N-terminal matrix-targeting sequence recognized by the Tom20/22 import receptor, is transferred through the Tom40 general import pore of the outer membrane and the inner-membrane Tim23/17 translocation complex. In addition to the matrix-targeting sequence, which is cleaved during import, CoxVa contains a hydrophobic stop-transfer anchor sequence. As the protein passes through the Tim23/17 channel, the stop-transfer anchor sequence blocks translocation of the C-terminus across the inner membrane. The membrane-anchored intermediate is then transferred laterally into the bilayer of the inner membrane, much like type I integral membrane proteins are incorporated into the ER membrane (see Figure 13-11).

FIGURE 13-27 Three pathways to the inner mitochondrial membrane from the cytosol. Proteins with different targeting sequences are directed to the inner membrane via different pathways. In all three pathways, proteins cross the outer membrane via the Tom40 general import pore. Proteins delivered by pathways A and B contain an N-terminal matrix-targeting sequence that is recognized by the $\mathrm{Tom20/22}$ import receptor in the outer membrane. Although both these pathways use the $\mathrm{Tim23/17}$ inner-membrane channel, they differ in that the entire precursor protein enters the matrix and is then redirected to the inner membrane in pathway B. Matrix Hsp70 plays a role similar to its role in the import of soluble matrix proteins (see Figure 13-23). Proteins delivered by pathway C contain internal sequences that are recognized by the $\mathrm{Tom70/Tom22}$ import receptor; a different inner-membrane translocation channel ($\mathrm{Tim22/54}$) is used in this pathway. Two intermembrane proteins (Tim9 and Tim10) facilitate transfer between the outer and inner channels. See the text for discussion. See R. E. Dalbey and A. Kuhn, 2000, *Annu. Rev. Cell Dev. Biol.* **16**:51; and N. Pfanner and A. Geissler, 2001, *Nat. Rev. Mol. Cell Biol.* **2**:339.

A second pathway to the inner membrane is used by proteins such as ATP synthase subunit 9, whose precursors contain both a matrix-targeting sequence and internal hydrophobic domains recognized by an inner-membrane protein termed *Oxa1*. This pathway is thought to involve translocation of at least a portion of the precursor into the matrix via the Tom40 and Tim23/17 channels. After cleavage of the matrix-targeting sequence, the protein is inserted into the inner membrane by a process that requires interaction with Oxa1 and perhaps other inner-membrane proteins (see Figure 13-27, path B). Oxa1 is related to a protein involved in inserting some plasma-membrane proteins in bacteria. This relatedness suggests that Oxa1 may have descended from the translocation machinery in the endosymbiotic bacterium that eventually became the mitochondrion. However, the proteins that form the inner-membrane channels in mitochondria are not related to the proteins in bacterial translocons. Oxa1 also participates in the inner-membrane insertion of certain proteins, such as subunit II of cytochrome oxidase, that are encoded by mitochondrial DNA and synthesized in the matrix by mitochondrial ribosomes.

The final pathway for insertion in the inner mitochondrial membrane is followed by multipass proteins that contain six membrane-spanning domains, such as the ATP/ADP antiporter. These proteins, which lack the usual N-terminal matrix-targeting sequence, contain multiple internal mitochondrial targeting sequences. After the internal sequences are recognized by a second

import receptor composed of outer-membrane proteins Tom70 and Tom22, the imported protein passes through the outer membrane via the general import pore (see Figure 13-27, path C). The protein then is transferred to a second translocation complex in the inner membrane composed of the Tim22, Tim18, and Tim54 proteins. Transfer to the Tim22/18/54 complex depends on a multimeric complex of two small proteins, Tim9 and Tim10, which reside in the intermembrane space. These small Tim proteins are thought to act as chaperones, guiding imported protein precursors from the general import pore to the Tim22/18/54 complex in the inner membrane by binding to their hydrophobic regions, preventing them from forming insoluble aggregates in the aqueous environment of the intermembrane space. Ultimately the Tim22/18/54 complex is responsible for incorporating the multiple hydrophobic segments of the imported protein into the inner membrane.

Intermembrane-Space Proteins

Two pathways deliver cytosolic proteins to the space between the inner and outer mitochondrial membranes. The major pathway is followed by proteins such as cytochrome b_2, whose precursors carry two different N-terminal targeting sequences, both of which are ultimately cleaved. The most N-terminal of the two sequences is a matrix-targeting sequence, which is removed by the matrix protease. The second targeting sequence is a hydrophobic segment

that blocks complete translocation of the protein across the inner membrane (Figure 13-28, path A). After the resulting membrane-embedded intermediate diffuses laterally away from the Tim23/17 translocation channel, a protease in the membrane cleaves the protein near the hydrophobic transmembrane segment, releasing the mature protein in a soluble form into the intermembrane space. Except for the second proteolytic cleavage, this pathway is similar to that of inner-membrane proteins such as CoxVa (see Figure 13-27, path A).

FIGURE 13-28 Two pathways to the mitochondrial intermembrane space. Pathway A, the major one for delivery of proteins from the cytosol to the intermembrane space, is similar to pathway A for delivery to the inner membrane (see Figure 13-26). The major difference is that the internal targeting sequence in these proteins, such as cytochrome b_2, is recognized

by an inner-membrane protease, which cleaves the protein on the intermembrane-space side of the membrane. The released protein then folds and binds to its heme cofactor within the intermembrane space. Pathway B is a specialized pathway for delivery of the proteins Tim9 and Tim10 to the intermembrane space. These proteins readily pass through the Tom40 general import pore, and once they are in the intermembrane space, they fold and form disulfide bonds that prevent reverse translocation through Tom40. The disulfide bonds are generated by Erv1 and are transferred to Tim9 and Tim10 by Mia40. See R. E. Dalbey and A. Kuhn, 2000, *Annu. Rev. Cell Dev. Biol.* **16**:51; N. Pfanner and A. Geissler, 2001, *Nat. Rev. Mol. Cell Biol.* **2**:339; and K. Tokatlidis, 2005, *Cell* **121**:965–967.

The small Tim9 and Tim10 proteins, which reside in the intermembrane space, illustrate a second pathway for targeting to the intermembrane space. Tim9 and Tim10 do not contain an N-terminal matrix-targeting sequence and are delivered directly to the intermembrane space via the general import pore without involvement of any inner-membrane translocation factors (see Figure 13-28, path B). Translocation through the Tom40 general import pore does not seem to be coupled to any energetically favorable process; however, once located in the intermembrane space, Tim9 and Tim10 proteins acquire two disulfide bonds each and fold into compact, stable structures. Apparently, the mechanism that drives their unidirectional translocation through the outer membrane involves passive diffusion through the outer membrane followed by folding and disulfide bond formation, which irreversibly traps the proteins in the intermembrane space. The process of disulfide bond formation in the intermembrane space resembles that in the ER lumen and involves a disulfide bond–generating protein, Erv1, and a disulfide transfer protein, Mia40.

Outer-Membrane Proteins

Many of the proteins that reside in the mitochondrial outer membrane, including the Tom40 pore itself and mitochondrial porin, have a β-barrel structure in which antiparallel β strands form hydrophobic transmembrane segments surrounding a central channel. Such proteins are incorporated into the outer membrane by first interacting with the general import pore, Tom40; they are then transferred to the SAM (*s*orting and *a*ssembly *m*achinery) complex, which is composed of at least three outer-membrane proteins. Presumably it is the very stable hydrophobic nature of β-barrel proteins that ultimately causes them to be stably incorporated into the outer membrane, but precisely how the SAM complex facilitates this process is not known.

Import of Chloroplast Stromal Proteins Is Similar to Import of Mitochondrial Matrix Proteins

The most abundant proteins found in the chloroplast stroma are the enzymes of the Calvin cycle, which function in fixing carbon dioxide during photosynthesis (see Chapter 12). The large (L) subunit of ribulose 1,5-bisphosphate carboxylase (rubisco) is encoded by chloroplast DNA and synthesized on chloroplast ribosomes in the stromal space. The small (S) subunit of rubisco and all the other

Calvin cycle enzymes are encoded by nuclear genes and transported to chloroplasts after their synthesis in the cytosol. The precursor forms of these stromal proteins contain an N-terminal *stromal-import* sequence (see Table 13-1).

Experiments with isolated chloroplasts, similar to those with mitochondria, have shown that the general process of stromal import depicted in the top half of Figure 13-29 is similar to that of protein import into the mitochondrial matrix. At least three chloroplast outer-membrane proteins are known to be essential for directing proteins to the stroma. These include a receptor that binds the stromal-import sequence made up of proteins, known as *Toc159* and *Toc34*, each of which has a GTPase domain on the cytosolic side of the outer membrane reminiscent of SRP and SRP receptor. The receptor transfers the stromal-import sequence to a translocation channel made up of Toc75. A complex of at least five chloroplast inner-membrane proteins known as the *Tic complex* forms the translocation channel for passage of proteins into the stromal space. Although these proteins are functionally analogous to the receptor and channel proteins of the mitochondria, they are not structurally homologous. The lack of sequence similarity between these chloroplast and mitochondrial proteins suggests that they may have arisen independently during evolution.

FIGURE 13-29 Transporting proteins to chloroplast thylakoids. Two of the four pathways for transporting proteins from the cytosol to the thylakoid lumen are shown here. In these pathways, unfolded precursors are delivered to the stroma via the same outer-membrane proteins that import stromal-localized proteins. Cleavage of the N-terminal stromal-import sequence by a stromal

protease then reveals the thylakoid-targeting sequence (step **1**). At this point the two pathways diverge. In the SRP-dependent pathway (*left*), plastocyanin and similar proteins are kept unfolded in the stromal space by a set of chaperones (not shown), and the thylakoid-targeting sequence binds to proteins that are closely related to the bacterial SRP, SRP receptor, and SecY translocon, which mediate movement into the thylakoid lumen (step **2a**). After the thylakoid-targeting sequence is removed in the thylakoid lumen by a separate endoprotease, the protein folds into its mature conformation (step **3a**). In the pH-dependent pathway (*right*), metal-binding proteins fold in the stroma, and complex redox cofactors are added (step **2b**). Two arginine residues (RR) at the N-terminus of the thylakoid-targeting sequence and a pH gradient across the inner membrane are required for transport of the folded protein into the thylakoid lumen (step **3b**). The translocon in the thylakoid membrane is composed of at least four proteins related to proteins in the bacterial plasma membrane. The thylakoid-targeting sequence containing the two arginine residues is cleaved in the thylakoid lumen (step **4b**). See R. Dalbey and C. Robinson, 1999, *Trends Biochem. Sci.* **24**:17; R. E. Dalbey and A. Kuhn, 2000, *Annu. Rev. Cell Dev. Biol.* **16**:51; and C. Robinson and A. Bolhuis, 2001, *Nat. Rev. Mol. Cell Biol.* **2**:350.

The available evidence suggests that chloroplast stromal proteins, like mitochondrial matrix proteins, are imported in the unfolded state. Import into the stroma depends on ATP hydrolysis catalyzed by a stromal Hsp70 chaperone whose function is similar to that of Hsp70 in the mitochondrial matrix and BiP in the ER lumen. Unlike mitochondria, chloroplasts do not generate an electrochemical gradient (proton-motive force) across their inner membrane. Thus protein import into the chloroplast stroma appears to be powered solely by ATP hydrolysis.

In addition to Hsp70, the stroma contains two other ATPases that may participate in protein import. These are a chloroplast version of the chaperone Hsp90, and a ring forming AAA+ ATPase known as *Hsp93*. Homologs of both proteins are known to catalyze energy-dependent protein-folding reactions in other contexts and it may be that chloroplast Hsp90 and Hsp93 participate in protein folding in the stroma, protein import into the stroma, or both.

Proteins Are Targeted to Thylakoids by Mechanisms Related to Bacterial Protein Translocation

In addition to the double membrane that surrounds them, chloroplasts contain a series of internal interconnected membranous sacs, the **thylakoids** (see Figure 12-33). All of the chemical reactions of photosynthesis take place in the thylakoid membrane or lumen and are catalyzed by the proteins that are localized to this specialized subcompartment. Many of these proteins are synthesized in the cytosol as precursors containing multiple targeting sequences. For example, plastocyanin and other proteins destined for the thylakoid lumen require the successive action of two targeting sequences. The first is an N-terminal stromal-import sequence that directs the protein to the stroma by the same pathway that imports the rubisco S subunit. The second sequence targets the protein from the stroma to the thylakoid

lumen. The role of these targeting sequences has been shown in experiments measuring the uptake of mutant proteins generated by recombinant DNA techniques into isolated chloroplasts. For instance, mutant plastocyanin that lacks the thylakoid-targeting sequence but contains an intact stromal-import sequence accumulates in the stroma and is not transported into the thylakoid lumen.

Four separate pathways for transporting proteins from the stroma into the thylakoid have been identified. All four pathways have been found to be closely related to analogous transport mechanisms in bacteria, illustrating the close evolutionary relationship between the thylakoid membrane and the bacterial plasma membrane. Transport of plastocyanin and related proteins into the thylakoid lumen from the stroma occurs by an SRP-dependent pathway that uses a translocon similar to SecY, the bacterial version of the Sec61 complex (Figure 13-29, *left*). A second pathway for transporting proteins into the thylakoid lumen involves a protein related to bacterial protein SecA, which uses the energy from ATP hydrolysis to drive protein translocation through the SecY translocon. A third pathway, which targets proteins to the thylakoid membrane, depends on a protein related to the mitochondrial Oxa1 protein and the homologous bacterial protein (see Figure 13-27, path B). Some proteins encoded by chloroplast DNA and synthesized in the stroma or transported into the stroma from the cytosol are inserted into the thylakoid membrane via this pathway.

Finally, thylakoid proteins that bind metal-containing cofactors follow another pathway into the thylakoid lumen (see Figure 13-29, *right*). The unfolded precursors of these proteins are first targeted to the stroma, where the N-terminal stromal-import sequence is cleaved off, and the protein then folds and binds its cofactor. A set of thylakoid-membrane proteins assists in translocating the folded protein and bound cofactor into the thylakoid lumen. This process is powered by the H^+ electrochemical gradient normally maintained across the thylakoid membrane. The thylakoid-targeting sequence that directs a protein to this pathway includes two closely spaced arginine residues that are crucial for recognition. Bacterial cells also have a mechanism for translocating folded proteins with a similar arginine-containing sequence across the plasma membrane, known as the *Tat* (*t*win-*a*rginine *t*ranslocation) pathway. The molecular mechanism whereby these large folded globular proteins are translocated across the thylakoid membrane is not fully understood, but the presence of a folded protein with an appropriate twin arginine signal appears to induce the oligomerization of Tat proteins in the membrane to form pore-like structures. In this respect, the Tat pathway resembles the pathway for the import of folded proteins into peroxisomes, described in the next section.

KEY CONCEPTS OF SECTION 13.4

Targeting of Proteins to Mitochondria and Chloroplasts

- Most mitochondrial and chloroplast proteins are encoded by nuclear genes, synthesized on cytosolic ribosomes, and imported post-translationally into the

organelles.

- All the information required to target a precursor protein from the cytosol to the mitochondrial matrix or chloroplast stroma is contained within its N-terminal targeting sequence. After protein import, the targeting sequence is removed by proteases within the matrix or stroma.
- Cytosolic chaperones maintain the precursors of mitochondrial and chloroplast proteins in an unfolded state. Only unfolded proteins can be imported into the organelles.
- Proteins destined for the mitochondrial matrix bind to receptors on the outer mitochondrial membrane and are then transferred to the general import pore (Tom40) in the outer membrane. Translocation takes place at sites where the outer and inner membranes of the organelles are close together and occurs through the outer and inner membranes concurrently. Translocation is driven by ATP hydrolysis by Hsp70 in the matrix (see Figure 13-24) and by the proton-motive force across the inner membrane.
- Proteins sorted to mitochondrial destinations other than the matrix usually contain two or more targeting sequences, one of which may be an N-terminal matrix-targeting sequence (see Figure 13-26).
- Some mitochondrial proteins destined for the intermembrane space or inner membrane are first imported into the matrix and then redirected; others never enter the matrix, but go directly to their final location.
- Protein import into the chloroplast stroma occurs through outer-membrane and inner-membrane translocation channels that are analogous in function to mitochondrial channels, but composed of proteins unrelated in sequence to the corresponding mitochondrial proteins.
- Proteins destined for the thylakoid have secondary targeting sequences. After entry of these proteins into the stroma, cleavage of the stromal-targeting sequences reveals the thylakoid-targeting sequences.
- The four known pathways for moving proteins from the chloroplast stroma to the thylakoid closely resemble translocation across the bacterial plasma membrane (see Figure 13-29). One of these systems can translocate folded proteins.

13.5 Targeting of Peroxisomal Proteins

Peroxisomes are small organelles bounded by a single membrane which surrounds a luminal space known as the *peroxisomal matrix*. Although peroxisomes have a simple structure, the biogenesis of peroxisomes is similar in fundamental outline to the biogenesis of the more complicated mitochondria and chloroplasts. Peroxisomal proteins, encoded by nuclear genes and synthesized on free ribosomes in the cytosol, are recognized by specific peroxisomal-targeting sequences. These sequences bind to a peroxisome-specific receptor protein and are then delivered either to the peroxisomal matrix or to the peroxisomal membrane by an energy-dependent targeting process.

The size and enzyme content of peroxisomes vary considerably among different kinds of cells. However, all peroxisomes contain enzymes that use molecular oxygen to oxidize various substrates such as fatty acids, breaking them down into smaller components for use in biosynthetic pathways. The hydrogen peroxide (H_2O_2) generated by these oxidation reactions is extremely reactive and potentially harmful to cellular components; however, the peroxisome contains other enzymes, such as catalase, that efficiently convert H_2O_2 into H_2O. In mammals, peroxisomes are most abundant in liver cells, where they constitute about 1–2 percent of the cell volume.

A Cytosolic Receptor Targets Proteins with an SKL Sequence at the C-Terminus to the Peroxisomal Matrix

Peroxisomal-targeting sequences were first identified by testing of peroxisomal proteins with deletions for a specific defect in peroxisomal targeting. In one early study, the gene for firefly luciferase was expressed in cultured insect cells, and the resulting protein was shown to be properly targeted to the peroxisome. However, expression of a gene missing a small portion of the sequence encoding the C-terminus of the protein led to luciferase that failed to be targeted to the peroxisome and remained in the cytoplasm. By testing various mutant luciferase proteins in this system, researchers discovered that the sequence Ser-Lys-Leu (SKL in one-letter code) or a related sequence at the C-terminus is necessary for peroxisomal targeting. Furthermore, addition of the SKL sequence to the C-terminus of a normally cytosolic protein leads to uptake of the altered protein by peroxisomes in cultured cells. All but a few of the many different peroxisomal proteins bear a sequence of this type, known as *peroxisomal-targeting sequence 1*, or simply *PTS1*.

The pathway for the import of catalase and other PTS1-bearing proteins into the peroxisomal matrix is depicted in Figure 13-30. In the cytosol, PTS1 binds to a receptor called *Pex5*. Pex5 has the remarkable property of being able to switch from a monomeric

soluble form to an oligomeric form embedded in the peroxisomal membrane in a complex with the membrane protein Pex14. In a manner that is not well understood, the PTS1-bearing protein is released from the oligomeric form of Pex5 into the interior of the peroxisome. This peroxisome import machinery, unlike most systems that mediate protein import into the ER, mitochondria, and chloroplasts, can translocate folded proteins across the membrane. For example, catalase assumes a folded conformation and binds to heme in the cytoplasm before traversing the peroxisomal membrane. Cell-free studies have shown that the peroxisome import machinery can transport large macromolecular objects, including gold particles about 9 nm in diameter, as long as they have a PTS1 tag attached to them. There is evidence that the size of oligomers of Pex5 bound to PTS1-bearing cargo molecules and Pex14 adjusts according to the size of the PTS1-bearing cargo molecules. The dynamic formation of oligomers is apparently the key mechanism by which PTS1-bearing cargo molecules can be accommodated without the formation of large stable pores that would disrupt the integrity of the peroxisomal membrane.

FIGURE 13-30 PTS1-directed import of peroxisomal matrix proteins. Step 1: Most peroxisomal matrix proteins contain a C-terminal PTS1 targeting sequence (red), which binds to the cytosolic receptor Pex5. Step 2: Pex5 with the bound matrix protein forms a multimeric complex with the Pex14 receptor located on the peroxisomal membrane. Step 3: After assembly of the matrix protein-Pex5-Pex14 complex, the matrix protein dissociates from Pex5 and is released into the peroxisomal matrix. Steps 4 and 5: Pex5 is then returned to the cytosol by a process that involves ubiquitinylation by the membrane proteins Pex2, Pex10, and Pex12, followed by ATP-dependent removal from the membrane by the AAA-ATPase proteins Pex1 and Pex6. Note that folded proteins can be imported into peroxisomes and that the targeting sequence is not removed in the matrix. See P. E. Purdue and P. B. Lazarow, 2001, *Annu. Rev.*

Cell Dev. Biol. **17**:701; S. Subramani et al., 2000, *Annu. Rev. Biochem.* **69**:399; and V. Dammai and S. Subramani, 2001, *Cell* **105**:187.

Once the PTS1-bearing cargo molecule is released into the interior of the peroxisome, the oligomeric complex of Pex5 and Pex14 is actively disassembled, thus releasing Pex5 back into the cytoplasm in a soluble state. Pex5 recycling involves modification of membrane-bound Pex5 by ubiquitinylation. A complex of the peroxisomal membrane proteins Pex10, Pex12, and Pex2 transfers a ubiquitin moiety to Pex5. The AAA ATPases Pex1 and Pex6, anchored to the peroxisomal membrane by Pex15, recognize ubiquitinylated Pex5 and use the energy from ATP hydrolysis to remove it from the oligomeric complex with Pex14 and release it into the cytosol. After removal of the ubiquitin modification, cytosolic Pex5 is ready to carry out another cycle of binding to a PTS1-bearing protein.

Peroxisomal import studies with purified components have shown that the binding of Pex5 to a PTS1-bearing protein, the assembly of an oligomeric complex of Pex5 and Pex14, and release of the PTS1-bearing protein into the interior of the peroxisome can all occur spontaneously without a source of chemical energy such as ATP. In contrast, both ubiquitin modification of Pex5 and the recycling of Pex5 by the AAA-ATPase require ATP hydrolysis. Evidently, in the process by which Pex5 delivers PTS1-bearing proteins to the peroxisome matrix by cycling between the cytosol and the peroxisomal membrane, it is the recycling step that uses energy to

power unidirectional translocation of cargo molecules into the peroxisomal matrix.

A few peroxisomal matrix proteins, such as thiolase, are synthesized as precursors with an N-terminal targeting sequence known as *PTS2*. These proteins bind to a different cytosolic receptor protein, but otherwise their import is thought to occur by the same mechanism as for PTS1-containing proteins.

Peroxisomal Membrane and Matrix Proteins Are Incorporated by Different Pathways

Autosomal recessive mutations that cause defective peroxisome assembly occur naturally in the human population. Such mutations can lead to severe developmental defects often associated with craniofacial abnormalities. In *Zellweger syndrome* and related disorders, for example, the transport of many or all proteins into the peroxisomal matrix is impaired: newly synthesized peroxisomal enzymes remain in the cytosol and are eventually degraded. Genetic analyses of cultured cells from patients with Zellweger syndrome and of yeast cells carrying similar mutations have identified more than 20 genes that are required for peroxisome biogenesis.

Studies with peroxisome-assembly mutants have shown that different pathways are used for importing peroxisomal matrix proteins and for inserting proteins into the peroxisomal membrane (Figure 13-31). For example, analysis of cells from some patients with Zellweger syndrome led to the identification of the gene encoding Pex5 as well as many of the Pex genes needed for recycling of Pex5. Mutant cells that are defective in any one of these proteins cannot incorporate matrix proteins into peroxisomes; nonetheless, the cells contain empty peroxisomes that have a normal complement of peroxisomal membrane proteins (Figure 13-31b). Mutations in any one of three other genes were found to block insertion of peroxisomal membrane proteins as well as import of matrix proteins (Figure 13-31c). These findings demonstrate that one set of proteins translocates soluble proteins into the peroxisomal matrix, but a different set is required for insertion of proteins into the peroxisomal membrane. This situation differs markedly from that of the ER, mitochondrion, and chloroplast, whose membrane proteins and soluble proteins share many of the same components for their import into these organelles.

EXPERIMENTAL FIGURE 13-31 Studies reveal different pathways for incorporation of peroxisomal membrane and matrix proteins. Cells were stained with fluorescent antibodies to PMP70, a peroxisomal membrane protein, or with fluorescent antibodies to catalase, a peroxisomal matrix protein, then viewed in a fluorescence microscope. (a) In wild-type cells, both peroxisomal membrane and matrix proteins are visible as bright foci in numerous peroxisomal bodies. (b) In cells from a Pex12-deficient patient,

PMP70 is localized normally to peroxisomal bodies, but catalase is not delivered to peroxisomes and is distributed uniformly throughout the cytosol with no bright foci, whereas (c) in cells from a Pex3-deficient patient, peroxisomal membranes cannot assemble, and as a consequence, peroxisomal bodies do not form. Thus both catalase and PMP70 are mislocalized to the cytosol.

KEY CONCEPTS OF SECTION 13.5

Targeting of Peroxisomal Proteins

- All luminal peroxisomal proteins are synthesized on free cytosolic ribosomes and incorporated into the organelle post-translationally.
- Most peroxisomal matrix proteins contain a C-terminal targeting sequence known as *PTS1*; a few have an N-terminal PTS2 targeting sequence. Neither targeting sequence is cleaved after import.
- All proteins destined for the peroxisomal matrix bind to a cytosolic receptor protein, which is Pex5 for PTS1-bearing proteins, and then are directed to common translocation machinery on the peroxisomal membrane (see Figure 13-30).
- Translocation of matrix proteins across the peroxisomal membrane depends on ATP hydrolysis, which is coupled to recycling of Pex5 from the peroxisomal membrane back to the cytosol.
- Unlike proteins imported to the ER, mitochondrion, or chloroplast, many peroxisomal matrix proteins fold in the cytosol and traverse the membrane in a folded conformation.
- Proteins destined for the peroxisomal membrane contain different targeting sequences than peroxisomal matrix proteins and are imported by a different pathway.

13.6 Transport into and out of the Nucleus

The nucleus is separated from the cytoplasm by two membranes, which form the nuclear envelope (see Figure 1-12a). The nuclear envelope is continuous with the ER and forms a part of it. Transport of proteins from the cytoplasm into the nucleus and movement of macromolecules, including mRNAs, tRNAs, and ribosomal subunits, out of the nucleus occurs through *nuclear pores*, which span both membranes of the nuclear envelope. Import of proteins into the nucleus shares some fundamental features with protein import into other organelles. For example, imported nuclear proteins carry specific targeting sequences known as *nuclear-localization signals (NLSs)*. However, proteins are imported into the nucleus in a folded state, and thus nuclear import differs fundamentally from protein translocation across the membranes of the ER, mitochondrion, and chloroplast, during which proteins are unfolded. In this section, we discuss the main mechanism by which proteins enter and exit the nucleus. We also discuss the process by which mRNAs and other ribonuclear protein complexes are exported from the nucleus, which differs mechanistically from nuclear protein import.

Large and Small Molecules Enter and Leave the Nucleus via Nuclear Pore

Complexes

Numerous nuclear pores perforate the nuclear envelope in all eukaryotic cells. Each nuclear pore is formed from an elaborate structure termed the **nuclear pore complex (NPC)**, which is one of the largest discrete protein assemblages in the cell. The total mass of the pore structure is 60,000–80,000 kDa in vertebrates, which is about 16 times larger than a ribosome. An NPC is made up of many copies of some 30 different proteins called **nucleoporins**. Electron micrographs of nuclear pore complexes reveal a membrane-embedded ring structure that surrounds a largely aqueous pore (Figure 13-32). Eight approximately 100-nm long filaments extend into the nucleoplasm with the distal ends of these filaments joined by a terminal ring, forming a structure called the *nuclear basket*. Cytoplasmic filaments extend from the cytoplasmic side of the NPC into the cytosol.

FIGURE 13-32 Nuclear pore complex at different levels of resolution. (a) Nuclear envelopes from the large nuclei of *Xenopus* oocytes, visualized by scanning electron microscopy. *Top:* View of the cytoplasmic face reveals the octagonal shape of the membrane-embedded portion of nuclear pore complexes. *Bottom:* View of the nucleoplasmic face shows the nuclear basket that extends from the membrane-embedded portion. (b) Cutaway model of the nuclear pore complex, showing the major structural features formed by membrane nucleoporins, structural nucleoporins, and FG-nucleoporins. (c) Sixteen copies of the Y-complex form a major part of the structural scaffold of the nuclear pore complex. The three-dimensional structure of the Y-complex is modeled into the pore structure. Note the twofold symmetry across the double membrane of the nucleus (*left*) and the eightfold rotational

symmetry around the axis of the pore (*right*). (d) The FG-nucleoporins have extended disordered structures that are composed of repeats of the sequence Phe–Gly interspersed with hydrophilic regions (*left*). The FG-nucleoporins are most abundant in the central part of the pore, and the FG-repeat sequences are thought to fill the central channel with a gel-like matrix (*right*). See K. Ribbeck and D. Görlich, 2001, *EMBO J.* **20**:1320–1330; and M. P. Rout and J. D. Atchison, 2001, *J. Biol. Chem.* **276**:16593.

[Part (a) Republished with permission from Elsevier, from V. Doye and E. Hurt, 1997, Nucleoporins to Nuclear Pore Complexes, Curr. Opin. Cell Biol. 9(3):401–411; permission conveyed through Copyright Clearance Center, Inc.]

Ions, small metabolites, and globular proteins up to about 40 kDa can diffuse passively through the central aqueous region of the nuclear pore complex. However, large proteins and ribonucleoprotein complexes cannot diffuse in and out of the nucleus. Rather, these macromolecules are actively transported through the NPC with the assistance of soluble transport proteins that bind macromolecules and also interact with nucleoporins. The capacity and efficiency of the NPC for such active transport is remarkable. In one minute, *each* NPC is estimated to import 60,000 protein molecules into the nucleus, while exporting 50–250 mRNA molecules, 10–20 ribosomal subunits, and 1000 tRNAs out of the nucleus.

In general terms, the nucleoporins are of three types: *structural nucleoporins, membrane nucleoporins*, and *FG-nucleoporins*. The structural nucleoporins form the scaffold of the nuclear pore, which is a ring of eightfold rotational symmetry that traverses both membranes of the nuclear envelope, creating an opening in the

middle for movement of macromolecules into and out of the nucleus. The inner and outer membranes of the nuclear envelope are connected at the NPC by a highly curved region of membrane that contains the embedded membrane nucleoporins (Figure 13-32b). A set of seven structural nucleoporins forms a Y-shaped structure about the size of the ribosome, known as the *Y-complex*. Sixteen copies of the Y-complex form the basic structural scaffold of the pore, which has bilateral symmetry across the nuclear envelope and eightfold rotational symmetry in the plane of the envelope (Figure 13-32c). A structural motif repeated several times within the Y-complex is closely related to a structure found in the COPII proteins that drive the formation of coated vesicles within cells (see Chapter 14). This primordial relationship between structural nucleoproteins and vesicle coat proteins suggests that the two types of membrane coat complexes share a common origin. The basic function of this element may be to form a protein lattice that deforms the membrane into a highly curved structure.

The **FG-nucleoporins**, which line the channel of the nuclear pore complex and are also found associated with the nuclear basket and the cytoplasmic filaments, contain multiple repeats of short hydrophobic sequences that are rich in phenylalanine (F) and glycine (G) residues (FG-repeats). The hydrophobic FG-repeats are thought to occur in regions of extended, otherwise hydrophilic polypeptide chains that fill the central transporter channel. The FG-nucleoporins are essential for the function of the NPC, but their

function appears to depend on a general property of these proteins rather than on a specific structure, since the NPC remains functional even if up to half of the FG-repeats have been deleted. Biophysical studies and dynamic computer modeling show that FG-repeats can have a disordered structure similar to that of an unfolded protein and are highly dynamic. Because of these properties, the central channel of the NPC can be thought of as being filled with a fluidlike phase that allows the diffusion of small molecules while excluding unchaperoned hydrophilic proteins larger than 40 kDa (Figure 13-32d).

Nuclear Transport Receptors Escort Proteins Containing Nuclear-Localization Signals into the Nucleus

All proteins found in the nucleus — such as histones, transcription factors, and DNA and RNA polymerases — are synthesized in the cytoplasm and imported into the nucleus through nuclear pore complexes. Such proteins contain a nuclear-localization signal (NLS) that directs their selective transport into the nucleus. NLSs were first discovered through the analysis of mutations of the gene for large T-antigen encoded by simian virus 40 (SV40). The wild-type form of large T-antigen is localized to the nucleus in virus-infected cells, whereas some mutated forms of large T-antigen accumulate in the cytoplasm. The mutations responsible for this altered cellular

localization all occur within a specific seven-residue sequence rich in basic amino acids near the C-terminus of the protein: Pro-Lys-Lys-Lys-Arg-Lys-Val. Experiments with chimeric proteins in which this sequence was fused to a cytosolic protein demonstrated that it directs transport into the nucleus and consequently functions as an NLS (Figure 13-33). NLS sequences were subsequently identified in numerous other proteins imported into the nucleus. Many of these sequences are similar to the basic NLS in SV40 large T-antigen, whereas others are chemically quite different. For instance, an NLS in the RNA-binding protein hnRNP A1 is hydrophobic. Accordingly, there are multiple mechanisms for the recognition of these very different sequences.

EXPERIMENTAL FIGURE 13-33 Nuclear-localization signals (NLSs) direct proteins to the cell nucleus. Cytoplasmic proteins can be transported to the nucleus if they are fused to a nuclear-localization signal. (a) Normal pyruvate kinase, here visualized by immunofluorescence after cultured cells were treated with a specific antibody (yellow), is localized to the cytoplasm. This very large cytosolic protein functions in carbohydrate metabolism. (b) When a chimeric pyruvate kinase containing the SV40 NLS at its N-terminus was expressed in cells, it was localized to the nucleus. The chimeric protein was expressed from a transfected engineered gene produced by fusing a viral gene fragment encoding the SV40 NLS to the pyruvate kinase gene.

[Republished with permission from Elsevier, from D. Kalderon et al., 1984, "A Short Amino Acid Sequence Able to Specify Nuclear Location," *Cell* **39**(3 Pt 2):499–509; permission conveyed through Copyright Clearance Center, Inc.]

Early work on the mechanism of nuclear import showed that proteins containing a positively charged NLS, similar to the one in SV40 large T-antigen, were efficiently transported into isolated nuclei only if they were provided with a cytosolic extract (Figure 13-34). Using this assay system, researchers purified two required cytosolic components, a nuclear transport receptor and Ran GTPase. **Nuclear transport receptors** bind to the NLS on a cargo protein to be transported into the nucleus; they also have affinity for FG-repeats on nucleoporins. Because of their affinity for FG-repeats, nuclear transport receptors and NLS-containing cargo proteins to which they are bound readily partition into the fluid phase of FG-repeats in the central channel of the NPC, whereas proteins of similar size that lack this property are excluded from the central channel. Nuclear transport receptors can be monomeric, consisting of a single polypeptide that can bind both to an NLS and to FG-

repeats, or they can be dimeric, with one subunit binding to the NLS and the other binding to FG-repeats.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 13-34 Cytosolic proteins are required for nuclear transport. The failure of nuclear transport to occur in permeabilized cultured cells in the absence of cell lysate demonstrates the involvement of soluble cytosolic components in the process. (a) Phase-contrast micrographs of untreated and digitonin-permeabilized HeLa cells. Treatment of a monolayer of cultured cells with the mild non-ionic detergent digitonin permeabilizes the plasma membrane so that cytosolic constituents leak out, but leaves the

nuclear envelope and NPCs intact. (b) Fluorescence micrographs of digitonin-permeabilized HeLa cells incubated with a fluorescent protein chemically coupled to a synthetic SV40 T-antigen NLS peptide in the presence and absence of cell lysate (cytosol). Accumulation of the transport substrate in the nucleus occurred only when cytosol was present (*right*).

[S. A. Adam, R. S. Marr, and L. Gerace, 1990, *J. Cell Biol.* **111**: 807–816; https://doi.org/10.1083/jcb.111.3.807.]

Ran is a small monomeric G protein that exists in either a GTP-bound or a GDP-bound conformation (see Figure 3-35). It is the cycling of Ran between GTP-bound and GDP-bound conformations, leading to the net hydrolysis of GTP to GDP, that ultimately provides the energy to drive unidirectional transport of macromolecules through the nuclear pore.

The mechanism for the import of cytoplasmic cargo proteins mediated by a nuclear transport receptor known as *importin* is shown in Figure 13-35. Free importin in the cytoplasm binds to its cognate NLS in a cargo protein, forming an importin-cargo complex. The cargo complex then efficiently partitions into the NPC channel as the importin interacts with FG-repeats. Once in the channel, the importin-cargo complex can rapidly reach the nucleoplasmic side of the channel by random diffusion, and there the importin interacts with Ran · GTP, which causes a conformational change in the importin that displaces the NLS, releasing the cargo protein into the nucleoplasm. The importin-Ran · GTP complex then diffuses back through the NPC. Once the importin-Ran · GTP complex reaches

the cytoplasmic side of the NPC, Ran interacts with a specific *GTPase-activating protein (Ran-GAP)* that is a component of the NPC cytoplasmic filaments. This interaction stimulates Ran to hydrolyze its bound GTP to GDP, which causes it to convert to a conformation that has low affinity for the importin, so that the importin is released into the cytoplasm, where it can participate in another cycle of import. Ran · GTP travels back through the pore to the nucleoplasm, where it encounters a specific *guanine nucleotide exchange factor (Ran-GEF)* that causes Ran to release its bound GDP in favor of GTP. The net result of this series of reactions is the coupling of the hydrolysis of GTP to the transfer of an NLS-bearing protein from the cytoplasm to the nuclear interior, thus providing the energy to drive nuclear import.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 13-35 Mechanism for nuclear import of proteins. In the cytoplasm (*top*), free importin binds to the NLS of a cargo protein, and the importin-cargo complex thus formed diffuses through the NPC by transiently interacting with FG-nucleoporins. In the nucleoplasm, Ran·GTP binds to the importin, causing a conformational change that decreases the importin's affinity for the NLS and releasing the cargo. To support another cycle of import, the importin-Ran·GTP complex is transported back to the cytoplasm. A GTPase-activating protein

(GAP) associated with the cytoplasmic filaments of the NPC stimulates Ran to hydrolyze the bound GTP. This generates a conformational change that causes Ran to dissociate from the nuclear transport receptor, which can then initiate another round of import. Ran·GDP is returned to the nucleoplasm, where a guanine nucleotide exchange factor (GEF) causes release of GDP and rebinding of GTP.

Although the importin-cargo complex travels through the pore by random diffusion, the overall process of transport of cargo into the nucleus is unidirectional. Because of the rapid dissociation of the complex when it reaches the nucleoplasm, there is a concentration gradient of importin-cargo complex across the NPC: high in the cytoplasm, where the complex assembles, and low in the nucleoplasm, where it dissociates. This concentration gradient is responsible for the unidirectional nature of nuclear import. A similar concentration gradient is responsible for driving importin from the nucleus back into the cytoplasm. The concentration of the importin-Ran·GTP complex is higher in the nucleoplasm, where it assembles, than on the cytoplasmic side of the NPC, where it dissociates. Ultimately, the direction of the transport processes depends on the localization of the Ran-GEF predominantly in the nucleoplasm and the Ran-GAP predominantly in the cytoplasm. Ran-GEF in the nucleoplasm maintains Ran in the Ran·GTP state, where it promotes dissociation of the cargo complex. Ran-GAP on the cytoplasmic side of the NPC converts Ran·GTP to Ran·GDP, dissociating the importin-Ran·GTP complex and releasing free importin into the cytosol.

A Second Type of Nuclear Transport Receptor Escorts Proteins Containing Nuclear-Export Signals out of the Nucleus

A mechanism very similar to the one we have just described is used to export proteins, tRNAs, and ribosomal subunits from the nucleus to the cytoplasm. This mechanism was initially elucidated by studies of certain ribonuclear protein complexes that shuttle between the nucleus and the cytoplasm. Such shuttling proteins contain a *nuclear-export signal (NES)* that stimulates their export from the nucleus to the cytoplasm through nuclear pores, in addition to an NLS that results in their uptake into the nucleus. Experiments with engineered hybrid genes encoding a nucleus-restricted protein fused to various segments of a shuttling protein have identified at least three different types of NESs: a leucine-rich sequence found in PKI (an inhibitor of protein kinase A) and in the Rev protein of human immunodeficiency virus (HIV), and two other sequences identified in two different heterogeneous ribonucleoprotein particles (hnRNPs). The precise structural features that determine the recognition of each type of sequence for nuclear export remain poorly understood.

The mechanism whereby shuttling proteins are exported from the nucleus is best understood for those containing a leucine-rich NES.

According to the current model, shown in Figure 13-36a, a specific nuclear transport receptor, called *exportin 1*, first forms a complex with Ran · GTP in the nucleus and then binds the NES in a cargo protein. Binding of exportin 1 to Ran · GTP causes a conformational change in exportin 1 that increases its affinity for the NES, so that a trimolecular cargo complex is formed. Like other nuclear transport receptors, exportin 1 interacts transiently with FG-repeats in FG-nucleoporins and diffuses through the NPC. The cargo complex dissociates when it encounters the Ran-GAP associated with the NPC cytoplasmic filaments, which stimulates Ran to hydrolyze the bound GTP, shifting it into a conformation that has low affinity for exportin 1. After Ran · GDP dissociates from the trimolecular cargo complex, exportin 1 changes its conformation to one that has low affinity for the NES, releasing the cargo into the cytosol. The direction of the export process is driven by this dissociation of the cargo from exportin 1 in the cytoplasm, which causes a concentration gradient of the cargo complex across the NPC that is high in the nucleoplasm and low in the cytoplasm. Exportin 1 and Ran · GDP are then transported back into the nucleus through the NPC.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 13-36 Ran-dependent and Ran-independent nuclear export. (a) Ran-dependent mechanism for nuclear export of cargo proteins containing a leucine-rich nuclear-export signal (NES). In the nucleoplasm (*bottom*), the protein exportin 1 binds cooperatively to the NES of the cargo protein to be transported and to $\mathrm{Ran} \cdot \mathrm{GTP}$. After the resulting cargo complex diffuses through an NPC via transient interactions with FG-repeats in FG-nucleoporins, the GAP associated with the NPC cytoplasmic filaments stimulates GTP hydrolysis, converting $\mathrm{Ran} \cdot \mathrm{GTP}$ to $\mathrm{Ran} \cdot \mathrm{GDP}$. The accompanying conformational change in Ran leads to dissociation of the complex. The NES-containing cargo protein is released into the cytosol, whereas exportin 1 and $\mathrm{Ran} \cdot \mathrm{GDP}$ are transported back into the nucleus through an NPC. Ran-GEF in the nucleoplasm then stimulates conversion of $\mathrm{Ran} \cdot \mathrm{GDP}$ to $\mathrm{Ran} \cdot \mathrm{GTP}$. (b) Ran-independent nuclear export of mRNAs. The heterodimeric $\mathrm{NXF1/NXT1}$ complex binds to mRNA-protein complexes (mRNPs) in the nucleus. $\mathrm{NXF1/NXT1}$ acts as a nuclear transport receptor and directs the associated mRNP to the central channel of the NPC by transiently interacting with FG-nucleoporins. An RNA helicase (Dbp5) located on the cytoplasmic side of the NPC removes NXF1 and NXT1 from the mRNA in a reaction that is powered by ATP hydrolysis. Free NXF1 and NXT1 proteins are recycled back into the nucleus by the Ran-dependent import process depicted in Figure 13-35.

By comparing this model for nuclear export with that in Figure 13-35 for nuclear import, we can see one obvious difference: $\mathrm{Ran} \cdot \mathrm{GTP}$ is part of the cargo complex during export, but not during import. Apart from this difference, the two transport processes are remarkably similar. In both processes, association of a nuclear transport receptor with $\mathrm{Ran} \cdot \mathrm{GTP}$ in the nucleoplasm causes a conformational change that affects its affinity for the transport signal. During import, the interaction causes release of the cargo, whereas during export, the interaction promotes association with the cargo. In both export and import, stimulation of $\mathrm{Ran} \cdot \mathrm{GTP}$

hydrolysis in the cytoplasm by Ran-GAP produces a conformational change in Ran that releases the nuclear transport receptor. During nuclear export, the cargo is also released. Localization of Ran-GAP and Ran-GEF to the cytoplasm and nucleus, respectively, is the basis for the unidirectional import and export of cargo proteins across the NPC.

In keeping with their similarity in function, the two types of nuclear transport receptors — importins and exportins — are highly homologous in sequence and structure. The family of nuclear transport receptors has 14 members in yeast and more than 20 in mammalian cells. The NESs or NLSs to which they bind have been determined for only a fraction of them. Some individual nuclear transport receptors function in both import and export.

A similar shuttling mechanism has been shown to export other cargoes from the nucleus. For example, exportin-t functions to export tRNAs. Exportin-t binds fully processed tRNAs in a complex with Ran · GTP that diffuses through NPCs and dissociates when it interacts with Ran-GAP in the NPC cytoplasmic filaments, releasing the tRNA into the cytosol. A Ran-dependent process is also required for the nuclear export of ribosomal subunits through NPCs once the protein and RNA components have been properly assembled in the nucleolus. Likewise, certain specific mRNAs that associate with particular hnRNP proteins can be exported by a Ran-dependent mechanism.

Most mRNAs Are Exported from the Nucleus by a Ran-Independent Mechanism

Once the processing of an mRNA is completed in the nucleus, it remains associated with specific proteins in a *messenger ribonuclear protein complex*, or *mRNP*. The principal transporter of mRNPs out of the nucleus is the **mRNP exporter**, a heterodimeric protein composed of a large subunit called *nuclear export factor* 1 *(NXF1)* and a small subunit called *nuclear export transporter* 1 *(NXT1)*. Multiple NXF1/NXT1 dimers bind to nuclear mRNPs through cooperative interactions with the RNA and other mRNP adapter proteins that associate with nascent pre-mRNAs during transcriptional elongation and pre-mRNA processing. This process adds a degree of quality control to mRNA export since NXF1/NXT1 dimers do not assemble onto the mRNP until it has all of the attributes of a properly and completely processed mRNA. Once incorporated into an mRNP, the subunits of NXF1/NXT1 in many respects act like a nuclear transport receptor that binds to an NLS or NES, since both NXF1 and NXT1 interact with the FG-repeats of FG-nucleoporins, and this interaction allows them to diffuse through the central channel of the NPC.

The process of mRNP export does not require Ran, and thus the unidirectional transport of mRNA out of the nucleus requires a

source of energy other than GTP hydrolysis by Ran. Once the mRNP-NXF1/NXT1 complex reaches the cytoplasmic side of the NPC, NXF1, and NXT1 dissociate from the mRNP with the help of the RNA helicase Dbp5, which is associated with cytoplasmic NPC filaments. Recall that RNA helicases use the energy derived from hydrolysis of ATP to move along RNA molecules, separating double-stranded RNA chains and dissociating RNA-protein complexes (see Chapter 5). This leads to the simple idea that Dpb5, which is associated with the cytoplasmic side of the nuclear pore complex, acts as an ATP-driven motor to remove NXF1/NXT1 from the mRNP complexes as they emerge on the cytoplasmic side of the NPC. The portions of an mRNP that have emerged into the cytosol and have been stripped of NXF1/NXT1 lack the ability to interact with FG-repeat nucleoporins. Thus an extended mRNP that transits the NPC cannot slide back into the nucleus, and the process of energy dependent removal of NXF1/NXT1 by Dbp5 helicase causes the mRNP to be progressively ratcheted into the cytoplasm. After being removed from the mRNP, the free NXF1 and NXT1 subunits are imported back into the nucleus by a process that depends on Ran and a nuclear transport receptor (Figure 13-36b).

KEY CONCEPTS OF SECTION 13.6

Transport into and out of the Nucleus

- The nuclear envelope contains numerous nuclear pore complexes (NPCs), which are large, complex structures composed of multiple copies of 30 different proteins called *nucleoporins* (see Figure 13-32).

- FG-nucleoporins, which contain multiple repeats of a short hydrophobic sequence (FG-repeats), fill the central transporter channel with a gel-like matrix that allows small molecules to pass but excludes macromolecules larger than 40 kDa.
- Active transport plays a role in the transport of all large proteins and RNAs through nuclear pores. This process requires the assistance of nuclear transport receptors that interact with both the transported molecule and FG-repeats of FG-nucleoporins.
- Proteins imported into or exported from the nucleus contain a specific amino acid sequence that functions as a nuclear-localization signal (NLS) or a nuclear-export signal (NES). Nucleus-restricted proteins contain an NLS but not an NES, whereas proteins that shuttle between the nucleus and cytoplasm contain both signals.
- Several different types of NESs and NLSs have been identified. Each type of nuclear-transport signal is thought to interact with a specific nuclear transport receptor belonging to a family of homologous proteins.
- A cargo protein bearing an NES or NLS translocates through nuclear pores bound to its cognate nuclear transport receptor. The transient interactions between nuclear transport receptors and FG-repeats allow very rapid diffusion of nuclear transport receptor–cargo complexes through the central channel of the NPC, which is filled with a hydrophobic matrix of FG-repeats.
- The unidirectional nature of protein export and import through nuclear pores results from the participation of Ran, a monomeric G protein that exists in different conformations when bound to GTP or GDP. Localization of the Ran guanine nucleotide exchange factor (Ran-GEF) in the nucleus and of the Ran GTPase-activating protein (Ran-GAP) in the cytoplasm creates a gradient with high concentrations of $\mathrm{Ran} \cdot \mathrm{GTP}$ in the nucleoplasm and of $\mathrm{Ran} \cdot \mathrm{GDP}$ in the cytoplasm. The interaction of a cargo complex with $\mathrm{Ran} \cdot \mathrm{GTP}$ in the nucleoplasm causes dissociation of the complex, releasing the cargo into the nucleoplasm (see Figure 13-35), whereas the assembly of an export cargo complex is stimulated by interaction with $\mathrm{Ran} \cdot \mathrm{GTP}$ in the nucleoplasm (see Figure 13-36).
- Most mRNPs are exported from the nucleus by binding to a heterodimeric mRNP exporter in the nucleoplasm that interacts with FG-repeats. The direction of transport (nucleus to cytoplasm) results from the action of an RNA helicase associated with the cytoplasmic filaments of the NPC that removes the heterodimeric mRNP exporter once the transport complex has reached the cytoplasm.

translocon
unfolded-protein response
vesicle-based trafficking

Review the Concepts

1. The following results were obtained in early studies on the translation of secretory proteins. Based on what we now know of this process, explain the reason why each result was observed.
   a. An in vitro translation system consisting only of mRNA and ribosomes resulted in secretory proteins that were larger than the identical protein when translated in a cell.
   b. A similar system that also included microsomes produced secretory proteins that were identical in size to those found in a cell.
   c. When the microsomes were added after in vitro translation, the synthesized proteins were again larger than those made in a cell.
2. Describe the source or sources of energy needed for unidirectional translocation across the membrane in (a) cotranslational translocation into the endoplasmic reticulum (ER); (b) post-translational translocation into the ER; and (c) translocation into the mitochondrial matrix.
3. Translocation into most organelles usually requires the activity of one or more cytosolic proteins. Describe the basic functions of three different cytosolic factors required for translocation into the ER, mitochondria, and peroxisomes, respectively.
4. Describe the typical principles used to identify topogenic sequences within proteins and how these principles can be used to develop computer algorithms. How does the identification of topogenic sequences lead to prediction of

the membrane arrangement of a multipass protein? What is the importance of the arrangement of positive charges relative to the membrane orientation of a signal-anchor sequence?

5. An abundance of misfolded proteins in the ER can result in the activation of the unfolded-protein response (UPR) and ER-associated degradation (ERAD) pathways. UPR decreases the abundance of unfolded proteins by altering gene expression of what type of genes? What is one manner in which ERAD may identify misfolded proteins? Why is dislocation of these misfolded proteins to the cytoplasm necessary?
6. Temperature-sensitive yeast mutants have been isolated that block each of the enzymatic steps in the synthesis of the dolichol-linked oligosaccharide precursor for *N*-linked glycosylation. Propose an explanation for why mutations that block synthesis of the intermediate with the structure dolichol-PP-$(\mathrm{GlcNAc})_2\mathrm{Man}_5$ completely prevent addition of *N*-linked oligosaccharide chains to secretory proteins, whereas mutations that block conversion of this intermediate into the completed precursor — dolichol-PP-$(\mathrm{GlcNAc})_2\mathrm{Man}_9\mathrm{Glc}_3$ — allow the addition of *N*-linked oligosaccharide chains to secretory glycoproteins.
7. Name four different proteins that facilitate the modification or folding of secretory proteins within the lumen of the ER. Indicate which of these proteins covalently modifies substrate proteins and which brings about only conformational changes in substrate proteins.

8. Describe what would happen to the precursor of a mitochondrial matrix protein in the following types of mitochondrial mutants: (a) a mutation in the Tom22 signal receptor; (b) a mutation in the Tom70 signal receptor; (c) a mutation in the matrix Hsp70; and (d) a mutation in the matrix signal peptidase.
9. Describe the similarities and differences between the mechanism of import into the mitochondrial matrix and the chloroplast stroma.
10. Design a set of experiments using chimeric proteins, composed of a mitochondrial precursor protein fused to dihydrofolate reductase (DHFR), that could be used to determine how much of the precursor protein must protrude into the mitochondrial matrix in order for the matrix-targeting sequence to be cleaved by the matrix-processing protease.
11. Peroxisomes contain enzymes that use molecular oxygen to oxidize various substrates, but in the process, hydrogen peroxide — a compound that can damage DNA and proteins — is formed. What is the name of the enzyme responsible for the breakdown of hydrogen peroxide to water? What is the mechanism of the import of this protein into the peroxisome, and what other proteins are involved?
12. Suppose that you have identified a new mutant cell line that lacks functional peroxisomes. Describe how you could determine experimentally whether the mutant is primarily defective for insertion/assembly of peroxisomal membrane proteins or matrix proteins.

13. The nuclear import of proteins larger than 40 kDa requires the presence of what amino acid sequence? Describe the mechanism of nuclear import. How are nuclear transport receptors able to get through the nuclear pore complex?
14. Why is localization of Ran-GAP in the nucleus and Ran-GEF in the cytoplasm necessary for unidirectional transport of cargo proteins containing an NES?

CHAPTER 14

Vesicular Traffic, Secretion, and Endocytosis

Structural models of the coat protein complexes for three types of transport vesicles. The coat complexes are responsible for sculpting the curvature of the vesicle membrane and for selecting the types of cargo proteins incorporated into the vesicle.

14.3 Early Stages of the Secretory Pathway
14.4 Later Stages of the Secretory Pathway
14.5 Receptor-Mediated Endocytosis
14.6 Directing Membrane Proteins and Cytosolic Materials to the Lysosome for Degradation

In the previous chapter, we explored how proteins are targeted to and translocated across the membranes of different intracellular organelles, including the endoplasmic reticulum (ER), mitochondria, chloroplasts, peroxisomes, and the nucleus. In this chapter, we turn our attention to the **secretory pathway** and the mechanisms of vesicular traffic that allow proteins to be secreted from the cell or delivered to the plasma membrane and the lysosomes. We also discuss the related processes of endocytosis, which delivers proteins and small molecules from outside the cell, or autophagy, which delivers organelles, proteins, and small molecules from the interior of the cell to the lysosome for degradation.

The secretory pathway is so named because it was initially studied in dedicated secretory cells that produce and secrete large quantities of proteins such as insulin or digestive enzymes to the outside of the cell. It was later discovered that the same pathway used for extracellular secretion of proteins delivers almost all newly synthesized membrane lipids and membrane proteins from the endoplasmic reticulum (ER) to the cell surface. Newly synthesized membrane proteins delivered to the plasma membrane include cell-surface receptors, transporters for nutrient uptake, and ion channels that maintain the proper ionic and electrochemical balance across the plasma membrane. Soluble secreted proteins also follow the secretory pathway to the cell surface, but instead of remaining embedded in the membrane, they are released into the aqueous extracellular environment. Examples of secreted proteins

include digestive enzymes, peptide hormones, serum proteins, and collagen.

The secretory pathway is also responsible for the distribution of particular sets of soluble and membrane proteins to the organelles that lie along the secretory pathway including the ER itself, the Golgi, the endosome, and the lysosome. As we saw in Chapter 13, the ER is the site of synthesis and folding of all proteins that enter the secretory pathway. In this chapter, we describe the principal function of the Golgi — remodeling of carbohydrate modifications of secretory proteins. The Golgi along with the endosome are two major hubs for distributing proteins to their final destination at the plasma membrane or the lysosome. The lysosome, as described in Chapter 4, is the organelle with an acidic interior that is used for degradation of proteins and storage of small molecules such as amino acids. Accordingly, the types of proteins delivered to the lysosomal membrane include subunits of the V-class proton pump that pumps H^+ from the cytosol into the acidic lumen of the lysosome, as well as transporters that release small molecules stored in the lysosome into the cytoplasm. Soluble proteins delivered by this pathway include lysosomal digestive enzymes such as proteases, glycosidases, phosphatases, and lipases.

For all of its apparent complexity, the organization and operation of the secretory pathway can be understood as the consequence of repeated variations of just two basic mechanistic themes. The first

theme is that transport of membrane and soluble proteins from one membrane-bounded compartment to another is mediated by coated **transport vesicles** that collect *cargo proteins* in buds arising from the membrane of one compartment and then deliver these cargo proteins to the next compartment by fusing with the membrane of that compartment. As we will see, different types of vesicles are responsible for each step in the secretory pathway, but the underlying mechanisms of budding of a coated vesicle from a donor membrane and the specific fusion with the appropriate target membrane are remarkably conserved, regardless of vesicle type. Importantly, as transport vesicles bud from one membrane and fuse with the next, the same face of the membrane remains oriented toward the cytosol. Therefore, once a protein has been inserted into the membrane or the lumen of the ER, that protein can be carried along the secretory pathway, moving from one organelle to the next without being translocated across another membrane or altering its orientation within the membrane.

The second repeated theme is that each organelle along the secretory pathway both receives new proteins delivered by targeted transport vesicle fusion and donates proteins that are removed from the organelle by transport vesicle budding. Because transport vesicles package and deliver only specific subsets of proteins, the outcome of vesicular trafficking to and from each organelle establishes the composition and thus the identity of each organelle.

The composition of the plasma membrane is determined by two pathways: vesicle transport to the plasma membrane by the secretory pathway, which is counterbalanced by removal of proteins and membrane by the **endocytic pathway** (Figure 14-1). Both selective delivery by secretory vesicles and selective removal of proteins by endocytic vesicles can be regulated, allowing the protein composition of the plasma membrane to be regulated in response to environmental or developmental signals. In addition, the endocytic pathway is used to ingest certain nutrients that are too large to be transported across the plasma membrane by one of the transport mechanisms discussed in Chapter 11. For example, the endocytic pathway is used in the uptake of cholesterol carried in LDL particles. In addition, the endocytic pathway can be used to remove receptor proteins from the cell surface as a way to down-regulate their activity.

FIGURE 14-1 Basic principles of vesicle trafficking govern the composition of the plasma membrane. 1 : Membranes and proteins are delivered to the plasma membrane by exocytosis of coated vesicles that bud from the Golgi complex. The types of proteins incorporated into these vesicles are determined by interactions with vesicle coat proteins. Note that the membrane proteins preserve their orientation in the membrane such that the domain facing the vesicle interior will ultimately face the exoplasmic face of the plasma membrane. Correspondingly, soluble proteins within the vesicle interior will be released into the extracellular space. 2 : Proteins and membrane are removed from the plasma membrane by the process of endocytosis by which coated vesicles bud from the plasma membrane into the cytoplasm. In this example, a membrane receptor protein is only incorporated into endocytic vesicles when bound to ligand. The overall composition of the plasma membrane is

controlled by a balance between the proteins that are selectively delivered by exocytic vesicles and the proteins that are removed by endocytic vesicles.

The overall organization of the individual vesicle trafficking steps to form the intersecting secretory and endocytic pathways is outlined in Figure 14-2. The first stage of the secretory pathway takes place in the rough endoplasmic reticulum (ER) (Figure 14-2, step **1**). As described in Chapter 13, newly synthesized soluble and membrane proteins are translocated into the ER, where they fold into their proper conformation and receive covalent modifications such as *N*-linked and *O*-linked carbohydrates and disulfide bonds. Once correctly folded and modified in the ER lumen, the newly synthesized proteins progress to the second stage of the secretory pathway: transport to and through the Golgi complex.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 14-2 Overview of the secretory and endocytic pathways of protein sorting. *Secretory pathway:* Synthesis of proteins bearing an ER signal sequence is completed on the rough ER (step **1**), and the newly made polypeptide chains are inserted into the ER membrane or cross it into the ER lumen (see Chapter 13). ER resident proteins such as BiP and PDI remain within the ER. The remainder are packaged into transport vesicles (step **2**) that bud from the ER and fuse to form new *cis*-Golgi cisternae. Missorted ER-resident proteins and vesicle membrane proteins that need to be reused are retrieved to the ER by vesicles (step **3**) that bud from the *cis*-Golgi and fuse with the ER. Each *cis*-Golgi cisterna, with its protein content, physically moves from the *cis* to the *trans* face of the Golgi complex (step **4**) by a nonvesicular process called *cisternal maturation*. Retrograde transport vesicles (step **5**) move Golgi-resident proteins to the proper Golgi compartments. In all cells, certain soluble proteins move to the cell surface in transport vesicles (step **6**) and are secreted continuously (constitutive secretion). In certain cell types, some soluble proteins are stored in secretory vesicles (step **7**) and are released only after the cell receives an appropriate neuronal or hormonal signal (regulated secretion). Lysosome-destined membrane and soluble proteins, which are transported in vesicles that bud from the *trans*-Golgi (step **8**), first move to the late endosome and then to the lysosome. *Endocytic pathway:* Plasma membrane proteins such as receptor proteins bound to their ligands can be taken up in vesicles that bud from the plasma membrane (step **9**) and move to the endosome from where they can either be recycled to the plasma membrane or be delivered to the lysosome for degradation.

The transport of cargo proteins from the ER to the Golgi occurs via **anterograde** (forward-moving) transport vesicles (Figure 14-2, step **2**). These vesicles fuse with one another to form a flattened membrane-bounded compartment known as the *cis-Golgi network* or *cis*-Golgi **cisterna** (a "cistern" is a container for holding water or other liquid). Certain proteins, mainly proteins that function in the ER, can be retrieved from the *cis*-Golgi cisterna and returned to the

ER via a different set of **retrograde** (backward-moving) transport vesicles (step **3**). In a manner reminiscent of an assembly line, the new *cis*-Golgi cisterna, with its cargo of proteins, physically moves from the *cis* position (nearest the ER) to the *trans* position (farthest from the ER), successively becoming first a *medial*-Golgi cisterna and then a *trans*-Golgi cisterna (step **4**). This process, known as **cisternal maturation**, primarily involves retrograde transport vesicles (step **5**), which retrieve enzymes and other Golgi-resident proteins from later to earlier Golgi cisternae, thereby maturing the *cis*-Golgi cisternae to *medial*-Golgi cisternae, and *medial*-Golgi cisternae to *trans*-Golgi cisternae. As secretory proteins move through the Golgi, their linked carbohydrates may be further modified by specific glycosyltransferases that are housed in the different Golgi compartments.

Proteins in the Golgi are eventually delivered to a complex network of membranes and vesicles termed the ***trans*-Golgi network**. The *trans*-Golgi network is a major branch point in the secretory pathway. It is at this stage that proteins are loaded into different kinds of vesicles and thereby trafficked to different destinations. Depending on which kind of vesicle the protein is loaded into, it will be transported to the plasma membrane and secreted immediately, stored for later release, or shipped to the lysosome (steps **6**–**8**). The process by which a vesicle moves to and fuses with the plasma membrane and releases its contents is known as **exocytosis**. In all cell types, at least some proteins are secreted continuously (a

process commonly called **constitutive secretion**), while others are stored inside the cell in specialized vesicles known as *secretory granules* until a signal for exocytosis causes them to be released (**regulated secretion**). Secretory proteins destined for lysosomes are first transported by vesicles from the *trans*-Golgi network to a compartment usually called the **late endosome**; the proteins are then transferred to the lysosome by direct fusion of the late endosome with the lysosomal membrane.

In this chapter, we first discuss the experimental techniques that have contributed to our knowledge of the secretory pathway and endocytosis. Then we focus on the general mechanisms of membrane budding and fusion. We will see that although different kinds of transport vesicles use distinct sets of proteins for their formation and fusion, all vesicles use the same general mechanism for budding, selection of particular sets of cargo molecules, and fusion with the appropriate target membrane. In the remaining sections of the chapter, we discuss both the early and late stages of the secretory pathway, including how specificity of targeting to different destinations is achieved. We conclude with a discussion of how proteins are transported to the lysosome by the endocytic pathway.

14.1 Techniques for Studying the Secretory Pathway

The key to understanding how proteins are transported through the organelles of the secretory pathway has been to develop a basic description of the function of transport vesicles and the mechanism by which they incorporate particular cargo molecules. Many components required for the formation and fusion of transport vesicles have been identified by a remarkable convergence of the genetic and biochemical approaches described in this section. All studies of intracellular protein trafficking employ some method for assaying the transport of a given protein from one compartment to another. We begin by describing how intracellular protein transport can be followed in live cells and then consider genetic and in vitro systems that have proved useful in elucidating the secretory pathway.

Transport of a Protein Through the Secretory Pathway Can Be Assayed in Live Cells

The classic studies of George Palade and his colleagues in the 1960s first established the order in which proteins move from one organelle to the next in the secretory pathway (see Classic

Experiment 14-1). These early studies also showed that secretory proteins are not released into the cytosol — the first indication that transported proteins are always associated with some type of membrane-bounded intermediate. In these experiments, radioactively labeled amino acids were injected into the pancreas of hamsters and the newly synthesized proteins that incorporated the labeled amino acids could be tracked as they made their way to the cell surface. At different times after injection, the animals were sacrificed and the pancreatic cells were immediately fixed with glutaraldehyde, sectioned, and subjected to autoradiography to visualize the locations of the radiolabeled proteins. Because the radioactive amino acids were administered in a short pulse, only those proteins synthesized immediately after injection were labeled, forming a distinct cohort of labeled proteins whose transport could be followed. In addition, because pancreatic acinar cells are dedicated secretory cells, almost all of the labeled amino acids in these cells were incorporated into secretory proteins, facilitating the observation of transported proteins.

Although autoradiography is rarely used today to localize proteins within cells, these early experiments illustrate the two basic requirements for any assay of intercompartmental transport. First, it is necessary to label a cohort of proteins in an early compartment so that their subsequent transfer to later compartments can be followed over time. Second, it is necessary to have a way to identify the compartment in which a labeled protein resides. Here we describe two modern experimental procedures for observing the

intracellular trafficking of a secretory protein in almost any type of cell.

In both procedures, a gene encoding an abundant membrane glycoprotein (G protein) from vesicular stomatitis virus (VSV) is introduced into cultured mammalian cells either by transfection or simply by infecting the cells with the virus. The transfected cells efficiently produce the VSV G protein, which is then inserted into the membrane of the ER. The use of a mutant gene encoding a temperature-sensitive VSV G protein allows researchers to turn subsequent transport of this protein on and off. At the restrictive temperature of 40 °C, newly made VSV G protein is misfolded and therefore retained within the ER by the quality-control mechanisms discussed in Chapter 13, whereas at the permissive temperature of 32 °C, the protein is correctly folded and transported through the secretory pathway to the cell surface. Importantly, the misfolding of the temperature-sensitive VSV G protein is reversible; thus when cells synthesizing mutant VSV G protein are grown at 40 °C and then shifted to 32 °C, the misfolded mutant VSV G protein that had accumulated in the ER will refold and be transported normally. This clever use of a temperature-sensitive mutation in effect defines a protein cohort whose subsequent transport can be followed.

In two variations of this basic procedure, transport of VSV G protein is monitored by different techniques. Studies using both of these modern trafficking assays came to the same conclusion as Palade's early experiments: in mammalian cells, vesicle-mediated transport

of a protein molecule from its site of synthesis on the rough ER to its arrival at the plasma membrane takes from 30 to 60 minutes.

Microscopy of GFP-Labeled VSV G Protein

One approach for observing the transport of VSV G protein employs a hybrid gene in which the viral gene is fused to the gene encoding green fluorescent protein (GFP), a naturally occurring fluorescent protein (see Chapter 4). The hybrid gene is transfected into cultured cells by techniques described in Chapter 6. When cells expressing the temperature-sensitive form of the hybrid protein (VSVG-GFP) are grown at the restrictive temperature, VSVG-GFP accumulates in the ER, which appears as a lacy network of membranes when the cells are observed in a fluorescent microscope. When the cells are subsequently shifted to a permissive temperature, the VSVG-GFP can be seen to move first to the membranes of the Golgi complex, which are densely concentrated at the edge of the nucleus, and then to the cell surface (Figure 14-3a). By observing the distribution of VSVG-GFP at different times after shifting cells to the permissive temperature, researchers have determined how long VSVG-GFP resides in each organelle of the secretory pathway (Figure 14-3b).

EXPERIMENTAL FIGURE 14-3 Protein transport through the secretory pathway can be visualized by fluorescence microscopy of cells producing a GFP-tagged membrane protein. Cultured cells were transfected with a hybrid gene encoding the viral membrane glycoprotein VSV G linked to the gene for green fluorescent protein (GFP). A temperature-sensitive mutant version of the viral gene was used so that newly made hybrid protein (VSVG-GFP) was retained in the ER at 40 °C but was released for transport at 32 °C. (a) Fluorescence micrographs of cells just before and at two times after they were shifted to the lower temperature. Movement of VSVG-GFP from the ER to the Golgi and finally to the cell surface occurred within 180 minutes. The scale bar is 5 μm. (b) Plot of the amount of VSVG-GFP in the endoplasmic reticulum (ER), Golgi, and plasma membrane (PM) at different times after the shift to the permissive temperature. The kinetics of transport from one organelle to another can be reconstructed from computer analysis of these data. The decrease in total fluorescence that occurs at later times probably results from slow inactivation of GFP fluorescence.

Detection of Compartment-Specific Oligosaccharide Modifications

A second way to follow the transport of secretory proteins takes advantage of modifications to their carbohydrate side chains that occur at different stages of the secretory pathway. To understand this approach, recall that many secretory proteins leaving the ER are carrying one or more copies of the *N*-linked oligosaccharide

$Man_8(GlcNAc)_2$, which are synthesized and attached to secretory proteins in the ER (see Figure 13-18). As a protein moves through the Golgi complex, different enzymes localized to the *cis-, medial-*, and *trans*-Golgi cisternae catalyze an ordered series of modifications to these core $Man_8(GlcNAc)_2$ chains, as discussed in a later section of this chapter. For instance, glycosidases that reside specifically in the *cis*-Golgi compartment sequentially trim mannose residues off the core oligosaccharide to yield a trimmed form, $Man_5(GlcNAc)_2$. By monitoring the trimming of the *N*-linked oligosaccharide, scientists can distinguish glycosylated VSV G protein that has entered the *cis*-Golgi from VSV G protein that remains in the ER. A specialized carbohydrate-cleaving enzyme known as *endoglycosidase D* enables the trimming of the *N*-linked oligosaccharide to be readily detected by gel electrophoresis; endoglycosidase D will cleave trimmed *cis*-Golgi-specific oligosaccharides from proteins, but will not cleave the core (untrimmed) oligosaccharide chains on secretory proteins within the ER (Figure 14-4a). Because a deglycosylated VSV G protein produced by endoglycosidase D digestion moves faster on an SDS gel than the corresponding glycosylated protein, these proteins can be readily distinguished (Figure 14-4b).

EXPERIMENTAL FIGURE 14-4 Transport of a membrane glycoprotein from the ER to the Golgi can be assayed based on sensitivity to cleavage by endoglycosidase D. Cells expressing a temperature-sensitive VSV G protein were labeled with a pulse of radioactive amino acids at the nonpermissive temperature so that the labeled protein was retained in the ER. At periodic times after a return to the permissive temperature of 32 °C, VSV G protein was extracted from cells and digested with endoglycosidase D. (a) As proteins move to the *cis*-Golgi from the ER, the core oligosaccharide $\mathrm{Man_8(GlcNAc)_2}$ is trimmed to $\mathrm{Man_5(GlcNAc)_2}$ by enzymes that reside in the *cis*-Golgi compartment. Endoglycosidase D cleaves the oligosaccharide chains from proteins processed in the *cis*-Golgi but not from proteins in the ER. (b) SDS-polyacrylamide gel electrophoresis of the digestion mixtures resolves the resistant, uncleaved (slower migrating) and sensitive, cleaved (faster migrating) forms of labeled VSV G protein. Initially, as this gel shows, all of the VSV G protein was resistant to digestion, but over time, an increasing fraction was sensitive to digestion, reflecting transport of the protein from the ER to the Golgi and its processing there. In control cells kept at 40 °C, only slow-moving, digestion-resistant VSV G protein was detected after 60 minutes (not shown). (c) A plot of the percentage of VSV G protein that is sensitive to digestion, derived from electrophoretic data, reveals the time course of ER-to-Golgi transport.

[Part (b) Data from C. J. Beckers et al., 1987, “Semi-Intact Cells Permeable to Macromolecules: Use in Reconstitution of Protein Transport from the Endoplasmic

Reticulum to the Golgi Complex," *Cell* **50**(4):523–34.]

This type of assay can be used to track movement of VSV G protein from the ER to the *cis*-Golgi in virus-infected cells pulse-labeled with radioactive amino acids. Immediately after labeling, all the labeled VSV G protein is still in the ER and, upon extraction, is resistant to digestion by endoglycosidase D. Over time, however, the fraction of the extracted glycoprotein that has received carbohydrate trimming in the *cis*-Golgi and is thus sensitive to digestion by endoglycosidase D increases. Note that transport of VSV G protein from the ER to the Golgi takes about 30 minutes, as measured either by the assay based on oligosaccharide processing or by fluorescence microscopy of VSVG-GFP (Figure 14-4c). A variety of assays based on specific carbohydrate modifications that occur in later Golgi compartments have been developed to measure progression of VSV G protein through each compartment of the Golgi complex.

Yeast Mutants Define Major Stages and Components of Vesicular Transport

The general organization of the secretory pathway and many of the molecular components required for vesicle trafficking are similar in all eukaryotic cells. Because of this conservation, genetic studies with yeast have been useful in identifying many of the proteins that participate in vesicular traffic. For yeast cells, as for all cells, the

secretory pathway is essential for transport and delivery of new protein and membrane to the cell surface. Thus genes encoding important components of the secretory pathway are essential for cell growth and can be studied only as conditional temperature-sensitive mutants, as described in Chapter 8.

A large number of yeast mutants were initially identified by their inability to secrete proteins at a nonpermissive temperature. When these temperature-sensitive ***secretion (sec)* mutants** are transferred from the lower permissive temperature to the higher nonpermissive temperature, they accumulate secretory proteins at the point in the secretory pathway blocked by the mutation. Analysis of such mutants identified five classes (A–E) characterized by protein accumulation in the cytosol, rough ER, small vesicles taking proteins from the ER to the Golgi complex, Golgi cisternae, or constitutive secretory vesicles (Figure 14-5). Subsequent characterization of *sec* mutants in these various classes has helped elucidate the fundamental components and molecular mechanisms of vesicle trafficking that we discuss in later sections.

EXPERIMENTAL FIGURE 14-5 Phenotypes of yeast *sec* mutants identified five stages in the secretory pathway. These temperature-sensitive mutants can be grouped into five classes (A–E) based on the site where newly made secretory proteins (red dots) accumulate when cells are shifted from the permissive temperature to the higher, nonpermissive one. Analysis of double mutants permitted the sequential order of the steps to be determined. Note that organelle structures before the stage blocked by a mutant are exaggerated because the *sec* mutants block movement of membranes as well as cargo. See P. Novick et al., 1981, *Cell* **25**:461; and C. A. Kaiser and R. Schekman, 1990, *Cell* **61**:723.

To determine the order of the steps in the pathway, researchers analyzed double *sec* mutants. For instance, when yeast cells contain mutations in both class B and class D functions, proteins accumulate in the rough ER, not in the Golgi cisternae. Because proteins accumulate at the earliest blocked step, this finding shows that class B mutations must act at an earlier point in the secretory pathway than class D mutations do. These studies confirmed that as a secreted protein is synthesized and processed, it moves sequentially from the cytosol to the rough ER, to ER-to-Golgi transport vesicles, to Golgi cisternae, to secretory vesicles, and finally is exocytosed.

Most importantly, the yeast *sec* mutants define many of the genes and encoded proteins that are required for vesicle budding and fusion at each of the major steps of the secretory pathway. Each of the individual steps in the secretory pathway is currently being studied in mechanistic detail, and biochemical assays and protein structural studies are being used to understand each of these steps in terms of the structure and function of individual protein molecules.

Cell-Free Transport Assays Allow Dissection of Individual Steps in Vesicular Transport

In vitro assays for intercompartmental transport are powerful complementary approaches to studies with yeast *sec* mutants for identifying and analyzing the cellular components responsible for vesicular trafficking. In one application of this approach, cultured mutant cells lacking one of the enzymes that modify *N*-linked oligosaccharide chains in the Golgi are infected with vesicular stomatitis virus, and the fate of the VSV G protein is followed. For example, if infected cells lack *N*-acetylglucosamine transferase I, they produce abundant amounts of VSV G protein but cannot add *N*-acetylglucosamine residues to the oligosaccharide chains in the *medial*-Golgi as wild-type cells do (Figure 14-6a). When Golgi membranes isolated from such mutant cells are mixed with Golgi membranes from wild-type, uninfected cells, the addition of *N*-acetylglucosamine to VSV G protein is restored (Figure 14-6b). This modification is the consequence of vesicular transport of *N*-acetylglucosamine transferase I from the wild-type *medial*-Golgi to the *cis*-Golgi isolated from virally infected mutant cells.

EXPERIMENTAL FIGURE 14-6 A cell-free assay demonstrates protein transport from one Golgi cisterna to another. (a) A mutant line of cultured fibroblasts is essential in this type of assay. In this example, the cells lack the enzyme *N*-acetylglucosamine transferase I (see step **2** in Figure 14-15). In wild-type cells, this enzyme is localized to the *medial*-Golgi and modifies *N*-linked oligosaccharides by the addition of one *N*-acetylglucosamine. In VSV-infected wild-type cells, the oligosaccharide on the viral G protein is modified to a typical complex oligosaccharide, as shown in the *trans*-Golgi panel. In infected mutant cells, however, the G protein reaches the cell surface with a simpler high-mannose oligosaccharide containing only two *N*-acetylglucosamine and five mannose residues. (b) When Golgi cisternae isolated from infected mutant cells are incubated with Golgi cisternae from normal, uninfected cells, the VSV G protein produced in vitro contains the additional *N*-acetylglucosamine. This modification is carried out by transferase enzyme that is moved by transport vesicles from the wild-type *medial*-Golgi cisternae to the mutant *cis*-Golgi cisternae in the reaction mixture. See W. E. Balch et al., 1984, *Cell* **39**:405 and 525; W. A. Braell et al., 1984, *Cell* **39**:511; and J. E. Rothman and T. Söllner, 1997, *Science* **276**:1212.

Proteins that play a role in Golgi transport have been identified by fractionation methods. Under appropriate conditions, a uniform population of the transport vesicles that move *N*-acetylglucosamine transferase I from the *medial*- to *cis*-Golgi can be separated from the donor wild-type Golgi membranes by centrifugation. By examining the proteins that are enriched in these vesicles, scientists have been

able to identify many of the integral membrane proteins and peripheral vesicle coat proteins that are the structural components of this type of vesicle. Moreover, fractionation of the cytosolic extract required for transport in cell-free reaction mixtures has permitted isolation of the various proteins required for formation of transport vesicles and of proteins required for the targeting and fusion of vesicles with appropriate acceptor membranes. In vitro assays similar in general design to the one shown in Figure 14-6 have been used to study the proteins that play a role at various transport steps in the secretory pathway.

KEY CONCEPTS OF SECTION 14.1

Techniques for Studying the Secretory Pathway

- All assays for following the trafficking of proteins through the secretory pathway require a way to label a cohort of secretory proteins and a way to identify the compartments where the labeled proteins are subsequently located.
- Transport of a fluorescently labeled protein along the secretory pathway can be observed by microscopy (see Figure 14-3). A temperature-sensitive mutant protein that is retained in the ER due to misfolding at the nonpermissive temperature will be released as a cohort for transport when cells are shifted to the permissive temperature.
- Alternatively, pulse labeling with radioactive amino acids can specifically label a cohort of newly made proteins in the ER and the transport of a radiolabeled protein can be tracked by following compartment-specific covalent modifications to the protein.
- Many of the components required for intracellular protein trafficking have been identified in yeast by analysis of temperature-sensitive *sec* mutants defective for the secretion of proteins at the nonpermissive temperature (see Figure 14-5).
- Cell-free assays for intercompartmental protein transport have allowed the biochemical dissection of individual steps of the secretory pathway. Such in vitro

reactions can be used to produce pure transport vesicles and to test the biochemical function of individual transport proteins.

14.2 Molecular Mechanisms of Vesicle Budding and Fusion

Small membrane-bounded vesicles that transport proteins from one organelle to another are the fundamental functional elements in the secretory and endocytic pathways (see Figure 14-1). These vesicles bud from the membrane of a particular *parent (donor) organelle* and fuse with the membrane of a particular *target (destination) organelle*. Although each step in the secretory and endocytic pathways employs a different type of vesicle, studies employing genetic and biochemical techniques have revealed that each of the different vesicular transport steps is simply a variation on a common theme. In this section, we explore the basic mechanisms underlying vesicle budding and fusion that all vesicle types have in common, before discussing the details unique to each step in the pathway.

Assembly of a Protein Coat Drives Vesicle Formation and Selection of Cargo Molecules

The budding of a vesicle from its parent membrane is triggered by the activation of a GTP-binding protein followed by the polymerization of soluble protein complexes on the membrane to form a proteinaceous vesicle coat (Figure 14-7a). Interactions

between the cytosolic portions of integral membrane proteins and the vesicle coat gather the appropriate cargo proteins into the forming vesicle. Thus the coat gives curvature to the membrane to form a vesicle and acts as the filter to determine which proteins are admitted into the vesicle.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 14-7 Overview of vesicle budding and fusion with a target membrane. (a) Budding is initiated by recruitment of a small GTP-binding protein to a patch

of donor membrane. Complexes of coat proteins in the cytosol then bind to the cytosolic domain of membrane cargo proteins, some of which also act as receptors that bind soluble proteins in the lumen, thereby recruiting luminal cargo proteins into the budding vesicle. (b) After being released and shedding its coat, a vesicle fuses with its target membrane in a process that involves interaction of cognate SNARE proteins.

Proteins responsible for the eventual fusion of a vesicle with the target membrane, known as **v-SNAREs**, are incorporated into the vesicle membrane during assembly of the vesicle coat. Once the coat is at least partially shed from a completed vesicle, v-SNARE proteins embedded in the vesicle membrane become accessible to join with cognate **t-SNAREs** in the target membrane to which the vesicle is docked. This joining brings the membranes into close apposition, allowing the two bilayers to fuse (Figure 14-7b). Regardless of target organelle, all transport vesicles use v-SNAREs and t-SNAREs to fuse.

Three major types of coated vesicles have been characterized, each with a different type of protein coat and each formed by reversible polymerization of a distinct set of protein subunits (Table 14-1). Each type of vesicle, named for its primary coat proteins, transports cargo proteins from particular parent organelles to particular target organelles:

TABLE 14-1 • Coated Vesicles Involved in Protein Trafficking

Vesicle	Transport Step	Coat Proteins	Associated

Type	Mediated		GTPase
COPII	ER to *cis*-Golgi	Sec23/Sec24 and Sec13/Sec31 complexes, Sec16	Sar1
COPI	*cis*-Golgi to ER later to earlier Golgi cisternae	Coatomers containing seven different COP subunits	ARF
Clathrin and adapter proteins[i]	*trans*-Golgi to endosome	$\text{Clathrin} + \text{AP1 complexes}$	ARF
	trans-Golgi to endosome	$\text{Clathrin} + \text{GGA}$	ARF
	Plasma membrane to endosome	$\text{Clathrin} + \text{AP2 complexes}$	ARF
	Golgi to lysosome, melanosome, or platelet vesicles	AP3 complexes	ARF

[i]Each type of AP complex consists of four different subunits. It is not known whether the coat of AP3 vesicles contains clathrin.

- **COPII** vesicles transport proteins from the ER to the Golgi.
- **COPI** vesicles mainly transport proteins in the retrograde direction between Golgi cisternae and from the *cis*-Golgi back to the ER.
- **Clathrin**-coated vesicles transport proteins from the plasma membrane (cell surface) and the *trans*-Golgi network to late endosomes.

Every vesicle-mediated trafficking step is thought to use some kind of vesicle coat; however, a specific coat protein complex has not been identified for every type of vesicle. For example, vesicles that move proteins from the *trans*-Golgi to the plasma membrane during either constitutive or regulated secretion exhibit a uniform size and morphology, which suggests that their formation is driven by assembly of a regular coat structure, yet researchers have not identified specific coat proteins surrounding these vesicles.

The general scheme of vesicle budding shown in Figure 14-7a applies to all three known types of coated vesicles. Experiments with isolated or artificial membranes and purified coat proteins have shown that polymerization of the coat proteins on the cytosolic face of the parent membrane is necessary to produce the high curvature of the membrane that is typical of a transport vesicle that is about 50 nm in diameter. Electron micrographs of in vitro budding reactions often reveal structures that exhibit discrete regions of the parent membrane bearing a dense coat accompanied by the curvature characteristic of a completed vesicle (Figure 14-8). Such structures, usually called *vesicle buds*, appear to be intermediates that are visible after the coat has begun to polymerize but before the completed vesicle pinches off from the parent membrane. The polymerized coat proteins form a curved lattice that drives the formation of a vesicle bud by adhering to the cytosolic face of the membrane.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 14-8 Vesicle buds can be visualized during in vitro budding reactions. When purified COPII coat components are incubated with isolated ER vesicles or artificial phospholipid vesicles (liposomes), polymerization of the coat proteins on the vesicle surface induces emergence of highly curved buds. In this electron micrograph of an in vitro budding reaction, note the distinct membrane coat, visible as a dark protein layer, present on the vesicle buds.

A Conserved Set of GTPase Switch Proteins Controls the Assembly of

Different Vesicle Coats

Using in vitro vesicle-budding reactions among isolated membranes and purified coat proteins, scientists have determined the minimum set of coat components required to form each of the three major types of vesicles. Although most of the coat proteins differ considerably from one type of vesicle to another, the coats of all three vesicles contain a small GTP-binding protein that acts as a regulatory subunit to control coat assembly (see Figure 14-7a). A GTP-binding protein known as **ARF protein** plays this role in COPI and clathrin-coated vesicles. A different but related GTP-binding protein known as *Sar1 protein* is present in the coat of COPII vesicles. Both ARF and Sar1 are monomeric proteins with a structure generally similar to that of Ras, a key intracellular signal-transducing protein (see Figure 16-12). ARF and Sar1 proteins, like Ras, belong to the GTPase superfamily of switch proteins that cycle between GDP-bound and GTP-bound forms (see Figure 3-9 to review the mechanism of GTPase switch proteins).

As depicted in Figure 14-9, activation of Sar1 by binding to GTP is the initial event that triggers assembly of the COPII vesicle coat. Note that Sar1 is the only GTPase switch protein activated at the ER membrane and thus only COPII-coated vesicles bud from the ER membrane. This initiating event begins with an ER membrane protein known as *Sec12*, which acts as a guanine nucleotide exchange factor (GEF) for Sar1 by catalyzing the release of GDP from

cytosolic Sar1·GDP and the binding of GTP. Sec12 apparently receives and integrates multiple as yet unknown signals, probably including the presence of cargo proteins that are ready to be transported at the ER membrane. Binding of GTP causes a conformational change in Sar1; this exposes its amphipathic N-terminus, which then becomes embedded in the phospholipid bilayer and tethers Sar1·GTP to the ER membrane (Figure 14-9, step **1**). The membrane-attached Sar1·GTP drives the polymerization of cytosolic complexes of COPII subunits on the membrane, eventually leading to formation of vesicle buds (step **2**). Once COPII vesicles are released from the donor membrane, the Sar1 GTPase activity hydrolyzes Sar1·GTP in the vesicle membrane to Sar1·GDP with the assistance of one of the coat subunits (step **3**). This hydrolysis triggers disassembly of the COPII coat (step **4**). Thus Sar1 couples a cycle of GTP binding and hydrolysis to the formation and then disassembly of the COPII coat.

FIGURE 14-9 Model for the role of Sar1 in the assembly and disassembly of the COPII coat. Step 1: Interaction of soluble GDP-bound Sar1 with the GEF Sec12, an ER integral membrane protein, catalyzes exchange of GTP for GDP on Sar1. The hydrophobic N-terminus of the GTP-bound form of Sar1 extends outward from the protein's surface and anchors Sar1 to the ER membrane. Step 2: Once attached to the membrane, Sar1 serves as a binding site for the Sec23/Sec24 coat protein complex. Membrane cargo proteins are recruited to the forming vesicle bud by binding of specific short sequences (sorting signals) in their cytosolic regions to sites on the Sec23/Sec24 complex. Some membrane cargo proteins also act as receptors that bind soluble proteins in the lumen. The coat is completed by assembly of a second type of coat complex composed of Sec13 and Sec31 (not shown). Step 3: After the vesicle coat is

complete, the Sec23 coat subunit promotes GTP hydrolysis by Sar1. Step **4**: Release of Sar1·GDP from the vesicle membrane causes disassembly of the coat. See S. Springer et al., 1999, *Cell* **97**:145.

ARF protein undergoes a similar cycle of nucleotide exchange and hydrolysis coupled to the assembly of vesicle coats composed either of COPI or of clathrin and other coat proteins (AP complexes), discussed later. A covalent protein modification known as a *myristate anchor* on the N-terminus of the ARF protein weakly tethers ARF·GDP to the Golgi membrane. When GTP is exchanged for the bound GDP by a GEF attached to the Golgi membrane, the resulting conformational change in ARF allows hydrophobic residues in its N-terminal segment to insert into the membrane bilayer. The resulting tight association of ARF·GTP with the membrane serves as the foundation for further coat assembly.

Drawing on the structural similarities of Sar1 and ARF to other small GTPase switch proteins, researchers have constructed genes encoding mutant versions of the two proteins that have predictable effects on vesicular traffic when transfected into cultured cells. For example, in cells expressing mutant versions of Sar1 or ARF that cannot hydrolyze GTP, vesicle coats form and vesicle buds pinch off. However, because the mutant proteins cannot trigger disassembly of the coat, all available coat subunits eventually become permanently assembled into coated vesicles that are unable to fuse with target membranes. Addition of a nonhydrolyzable GTP analog to in vitro vesicle-budding reactions causes a similar blocking of coat

disassembly. The vesicles that form in such reactions have coats that never dissociate, allowing their composition and structure to be more readily analyzed. The purified COPI vesicles shown in Figure 14-10 were produced in such a budding reaction.

Courtesy of L. Orci (University of Geneva, Switzerland).

EXPERIMENTAL FIGURE 14-10 Coated vesicles accumulate during in vitro budding reactions in the presence of a nonhydrolyzable analog of GTP. When isolated Golgi membranes are incubated with a cytosolic extract containing COPI coat proteins, vesicles form and bud off from the membranes. Inclusion of a nonhydrolyzable

analog of GTP in the budding reaction prevents disassembly of the coat after vesicle release. This micrograph shows COPI vesicles generated in such a reaction and separated from membranes by centrifugation. Coated vesicles prepared in this way can be analyzed to determine their components and properties.

A second general function of small GTPases in vesicle formation is in the pinching off of a completed vesicle from the parent membrane. In vitro budding experiments show that the Sar1 GTPase that accumulates at the neck of the budding vesicle is required for the pinching off of COPII vesicles and that the ARF GTPase similarly drives the pinching off of COPI vesicles. The mechanism by which these small GTPases convert the energy from GTP hydrolysis to a mechanical force to complete the pinching off of the membrane is not understood. As we will see in Section 14.4, a large polymeric GTPase known as *dynamin* plays this role in clathrin-coated vesicles.

Targeting Sequences on Cargo Proteins Make Specific Molecular Contacts with Coat Proteins

In order for transport vesicles to move specific proteins from one compartment to the next, vesicle buds must be able to discriminate among potential membrane and soluble cargo proteins, accepting only those cargo proteins that should advance to the next compartment and excluding those that should remain as residents in the donor compartment. In addition to sculpting the curvature of

a donor membrane, the vesicle coat functions in selecting specific proteins as cargo. Membrane cargo proteins and soluble cargo proteins carry two different kinds of **sorting signals.** The sorting signals for membrane cargo proteins usually lie in the cytosolic portion of the protein and bind to one or another of the vesicle coat proteins (see Figure 14-7a). The polymerized coat thus acts as an affinity matrix to cluster selected membrane cargo proteins into forming vesicle buds. Because soluble proteins within the lumen of the parent organelle cannot contact the coat directly, they require a different kind of sorting signal. Soluble luminal proteins often contain what can be thought of as *luminal sorting signals*, which bind to the luminal domains of certain membrane cargo proteins. The properties of some of the known sorting signals in membrane and soluble proteins are summarized in Table 14-2. We describe the role of these signals in more detail in later sections.

TABLE 14-2 • Known Sorting Signals That Direct Proteins to Specific Transport Vesicles

Signal Sequence[ii]	Signal-Bearing Protein	Proteins with Signal	Signal Receptor
Cytoplasmic Sorting Signals			
Lys-Lys-X-X (KKXX)	ER-resident membrane proteins	COPI α and β subunits	COPI
Di-arginine (X-Arg-Arg-X)	ER-resident membrane proteins	COPI α and β subunits	COPI

Di-acidic (e.g., Asp-X-Glu)	Cargo membrane proteins in ER	COPII Sec24 subunit	COPII
Asn-Pro-X-Tyr (NPXY)	LDL receptor in plasma membrane	AP2 complex	Clathrin/AP2
Tyr-X-X-Φ (YXXΦ)	Membrane proteins in *trans*-Golgi	AP1 (μ1 subunit)	Clathrin/AP1
	Plasma membrane proteins	AP2 (μ2 subunit)	Clathrin/AP2
Leu-Leu (LL)	Plasma membrane proteins	AP2 complexes	Clathrin/AP2
Luminal Sorting Signals			
Lys-Asp-Glu-Leu (KDEL)	ER-resident soluble proteins	KDEL receptor in *cis*-Golgi membrane	COPI
Mannose 6-phosphate (M6P)	Soluble lysosomal enzymes after processing in *cis*-Golgi	M6P receptor in *trans*-Golgi membrane	Clathrin/AP1
	Secreted lysosomal enzymes	M6P receptor in plasma membrane	Clathrin/AP2

[ii] $\mathrm{X} = \text{any amino acid};\ \Phi = \text{hydrophobic amino acid}$. Single-letter amino acid abbreviations are in parentheses.

Rab GTPases Control Docking of Vesicles on Target Membranes

A second set of small GTP-binding proteins, known as **Rab proteins**, associate with transport vesicles and act as key regulators of vesicle trafficking to and fusion with the appropriate target membrane. Like

Sar1 and ARF, Rab proteins belong to the GTPase superfamily of switch proteins. Rab proteins also contain an isoprenoid anchor that allows them to become tethered to the vesicle membrane. Association of an activated Rab protein with a specific vesicle type is generally a two-step process. In the first step, cytosolic Rab·GDP is targeted to the appropriate vesicle, becoming attached there by insertion of its isoprenoid anchor into the vesicle membrane. Often this attachment step is facilitated by a protein that can associate with Rab·GDP along with its isoprenoid anchor, usually known as a *guanine nucleotide dissociation inhibitor (GDI)*. In the second step, a specific GEF located in the vesicle membrane converts membrane-bound Rab·GDP to Rab·GTP. Once localized and activated in this way, Rab·GTP is enabled to bind to a variety of different proteins, known as *Rab effectors*. Binding of Rab·GTP to a Rab effector can ultimately lead to docking of the vesicle on an appropriate target membrane (Figure 14-11a, step **1**). After vesicle fusion occurs, the GTP bound to the Rab protein is hydrolyzed to GDP, triggering the release of Rab·GDP, which can then undergo another cycle of GDP-GTP exchange, binding, and hydrolysis.

FIGURE 14-11 Model for docking and fusion of transport vesicles with their target membranes. (a) The proteins shown in this example participate in fusion of secretory vesicles with the plasma membrane, but similar proteins mediate all vesicle-fusion events.

Step **1**: A Rab protein tethered via a lipid anchor to a secretory vesicle binds to an effector protein complex on the plasma membrane, thereby docking the transport vesicle on the appropriate target membrane. Step **2**: A v-SNARE protein (in this case, VAMP) interacts with the cytosolic domains of the cognate t-SNAREs (in this case, syntaxin and SNAP-25). The very stable coiled-coil SNARE complexes that are formed hold the vesicle close to the target membrane. Step **3**: Fusion of the two membranes immediately follows formation of SNARE complexes, first by fusion of one leaflet of the bilayer to form a hemi-fused state (**3a**), followed by fusion of the second leaflet (**3b**). Step **4**: Following membrane fusion, NSF, in conjunction with α-SNAP, binds to the SNARE complexes. The NSF-catalyzed hydrolysis of ATP then drives dissociation of the SNARE complexes, freeing the SNARE proteins for another round of vesicle fusion. Also at this time, Rab·GTP is hydrolyzed to Rab·GDP and dissociates from the Rab effector (not shown). (b) The SNARE complex. Numerous noncovalent interactions between four long α helices, two from SNAP-25 and one each from syntaxin and VAMP, stabilize the coiled-coil structure. See J. E. Rothman and T. Söllner, 1997, *Science* **276**:1212; Y. A. Chen and R. H. Scheller, 2001, *Nat. Rev. Mol. Cell Biol.* **2**:98; and W. Weis and R. Scheller, 1998, *Nature* **395**:328.

[Part (b) Data from I. Fernandez et al., 1998, *Cell* **94**:841–849, PDB ID 1br0; and R. B. Sutton et al., 1998, *Nature* **395**:347–353, PDB ID 1sfc.]

A well-understood example of a Rab protein that enables vesicle fusion with the correct target membrane is the Sec4 protein of yeast, which specifically tags secretory vesicles, enabling them to fuse with the plasma membrane. In experiments, yeast cells expressing mutant Sec4 proteins accumulate secretory vesicles that are unable to fuse with the plasma membrane (class E mutants in Figure 14-5). Sec4·GDP binds to secretory vesicles, where it is activated to Sec4·GTP by its cognate GEF, which is itself located on secretory vesicles. Sec4·GTP, in turn, binds to its effector, a large tethering complex composed of eight subunits, known as the *exocyst*.

Tethering of secretory vesicles to the exocyst by binding of Sec4·GTP ultimately leads to vesicle fusion with the plasma membrane.

In mammalian cells, Rab5 protein is localized to endocytic vesicles, also known as *early endosomes*. These uncoated vesicles form from clathrin-coated vesicles just after they bud from the plasma membrane during endocytosis (see Figure 14-2, step **9**). The fusion of early endosomes with one another in cell-free systems requires the presence of Rab5, and addition of Rab5 and GTP to cell-free extracts accelerates the rate at which these vesicles fuse with one another. A long coiled protein known as *EEA1 (e*arly *e*ndosome *a*ntigen *1*), which resides on the membrane of the early endosome, functions as the effector for Rab5. In this case, Rab5·GTP on one endocytic vesicle is thought to bind specifically to EEA1 on the membrane of another endocytic vesicle, setting the stage for fusion of the two vesicles.

Every type of transport vesicle appears to be labeled with one or more specific Rab proteins. These Rab proteins, through their specific association with effectors that are membrane tethers and molecular motors, ensure that the vesicles are directed to the correct target membrane address (Table 14-3). The tracks on which the molecular motors run to deliver the vesicles to their destinations — microfilaments — will be discussed in Chapter 17.

TABLE 14-3 • Rab Proteins Involved in Vesicle Tethering and Vesicle

Movement

Rab Protein	Transport Step	Effector Proteins
Rab1/Ypt1	ER to *cis*-Golgi	TRAPP complex and GM130 complex in *cis*-Golgi
Sec4	*trans*-Golgi to plasma membrane	Exocyst on plasma membrane and Type V Myosin
Rab5	Plasma membrane to endosome	EEA1 tether on endosome
Rab6	Golgi movement along microtubules	Kinesin
Rab27	Melanosome movement to cell periphery	Type V Myosin

Paired Sets of SNARE Proteins Mediate Fusion of Vesicles with Target Membranes

As noted previously, shortly after a vesicle buds off from the donor membrane, the vesicle coat disassembles to uncover a vesicle-specific membrane protein, a v-SNARE (see Figure 14-7b). Likewise, each type of target membrane in a cell contains t-SNARE membrane proteins, which interact specifically with v-SNAREs. After Rab-mediated docking of a vesicle on its target membrane, the

interaction of cognate SNAREs brings the two membranes close enough together that they can fuse.

One of the best understood examples of SNARE-mediated fusion occurs during exocytosis of secreted proteins (see Figure 14-11a, steps **1** and **3**). In this case, the v-SNARE, known as *VAMP* (*v*esicle-*a*ssociated *m*embrane *p*rotein), is incorporated into secretory vesicles as they bud from the *trans*-Golgi network. The t-SNAREs are *syntaxin*, an integral membrane protein in the plasma membrane, and *SNAP-25*, which is attached to the plasma membrane by a hydrophobic lipid anchor in the middle of the protein. The cytosolic region in each of these three SNARE proteins contains a repeating heptad sequence that allows four α helices — one from VAMP, one from syntaxin, and two from SNAP-25 — to coil around one another to form a four-helix bundle (Figure 14-11b). The unusual stability of this bundled SNARE complex is conferred by the arrangement of hydrophobic and charged amino acid residues in the heptad repeats. The hydrophobic amino acids are buried in the central core of the bundle, and amino acids of opposite charge are aligned to form favorable electrostatic interactions between helices. As multiple four-helix bundles form, the embedded transmembrane domains of VAMP and syntaxin pull the vesicle and target membranes together into very close apposition. The energetically favorable formation of four-helix bundles can overcome the electrostatic repulsion of the generally negatively charged phospholipid head groups in the vesicle and target membranes,

allowing the hydrophobic interiors of the two membranes to come into contact, creating an opening between the two membranes, and ultimately causing the vesicle membrane to fuse with the target membrane.

In vitro experiments have shown that when liposomes containing purified VAMP are incubated with other liposomes containing syntaxin and SNAP-25, the two classes of membranes fuse, albeit slowly. This finding is strong evidence that the close apposition of membranes resulting from formation of SNARE complexes is sufficient to bring about membrane fusion. Fusion of a vesicle and target membrane occurs more rapidly and efficiently in the cell than it does in liposome experiments in which fusion is catalyzed only by SNARE proteins. The likely explanation for this difference is that in the cell, other proteins, such as Rab proteins and their effectors, are involved in targeting vesicles to the correct membrane.

Yeast cells, like all eukaryotic cells, express more than 20 different related v-SNARE and t-SNARE proteins. Analyses of yeast mutants defective in each of the SNARE genes have identified specific membrane-fusion events in which each SNARE protein participates. For all fusion events that have been examined, the SNAREs form four-helix bundled complexes similar to the VAMP/syntaxin/SNAP-25 complexes that mediate fusion of secretory vesicles with the plasma membrane. However, in other fusion events (e.g., fusion of COPII vesicles with the *cis*-Golgi network), each participating SNARE

protein contributes only one α helix to the bundle (unlike SNAP-25, which contributes two helices); in these cases, the SNARE complexes comprise one v-SNARE and three t-SNARE molecules.

Using the in vitro liposome fusion assay, researchers have tested the ability of various combinations of individual v-SNARE and t-SNARE proteins to mediate fusion of donor and target membranes. Of the very large number of different combinations tested, only a small number could efficiently mediate membrane fusion. To a remarkable degree, the functional combinations of v-SNAREs and t-SNAREs revealed in these in vitro experiments correspond to the actual SNARE protein interactions that mediate known membrane-fusion events in the yeast cell. Thus together with the specificity of interaction between Rab and Rab effector proteins, the specificity of the interaction between SNARE proteins can account for most, if not all, of the specificity of fusion between a particular vesicle type and its target membrane.

Dissociation of SNARE Complexes After Membrane Fusion Is Driven by ATP Hydrolysis

After a vesicle and its target membrane have fused, the SNARE complexes must dissociate to make the individual SNARE proteins available for additional fusion events. Because of the stability of

SNARE complexes, which are held together by numerous noncovalent intermolecular interactions, their dissociation depends on additional proteins and the input of energy.

The first clue that dissociation of SNARE complexes required the assistance of other proteins came from in vitro transport reactions depleted of certain cytosolic proteins. The observed accumulation of vesicles in these reactions indicated that vesicles could form under these conditions, but were unable to fuse with a target membrane. Eventually two proteins, designated *NSF* and *α-SNAP*, were found to be required for ongoing vesicle fusion in the in vitro transport reaction.

Yeast mutants have also contributed to our understanding of SNARE function. Among the class C yeast *sec* mutants are strains that lack functional Sec18 or Sec17, the yeast counterparts of mammalian NSF and α-SNAP, respectively. When these class C mutants are kept at the nonpermissive temperature, they accumulate ER-to-Golgi transport vesicles; when the cells are shifted to the lower, permissive temperature, the accumulated vesicles are able to fuse with the *cis*-Golgi.

Subsequent to the initial biochemical and genetic studies that identified NSF and α-SNAP, more sophisticated in vitro transport assays were developed. Using these newer assays, researchers have shown that NSF and α-SNAP proteins are not necessary for actual

membrane fusion, but rather are required for regeneration of free SNARE proteins. NSF, a hexamer of identical subunits, associates with a SNARE complex with the aid of α-SNAP (*s*oluble *N*SF *a*ttachment *p*rotein). The bound NSF then hydrolyzes ATP, releasing sufficient energy to dissociate the SNARE complex (see Figure 14-11a, step **4**). Evidently, the defects in vesicle fusion observed in the earlier in vitro fusion assays and in the yeast mutants after a loss of Sec17 or Sec18 were a consequence of free SNARE proteins rapidly becoming sequestered in undissociated SNARE complexes and thus being unavailable to mediate membrane fusion.

KEY CONCEPTS OF SECTION 14.2

Molecular Mechanisms of Vesicle Budding and Fusion

- The three well-characterized types of transport vesicles — COPI, COPII, and clathrin-coated vesicles — are distinguished by the proteins that form their coats and the transport routes they mediate (see Table 14-1).
- All types of coated vesicles are formed by polymerization of cytosolic coat proteins on a parent (donor) membrane to form vesicle buds that eventually pinch off from the membrane to release a complete vesicle. Shortly after vesicle release, the coat is shed, exposing proteins required for fusion with the target membrane (see Figure 14-7).
- Small GTP-binding proteins (ARF or Sar1) belonging to the GTPase superfamily control polymerization of coat proteins, the initial step in vesicle budding (see Figure 14-9). After vesicles are released from the donor membrane, hydrolysis of GTP bound to ARF or Sar1 triggers disassembly of the vesicle coats.
- Specific sorting signals in membrane and luminal proteins in donor organelles interact with coat proteins during vesicle budding, thereby recruiting cargo proteins to vesicles (see Table 14-2).
- A second set of GTP-binding proteins, the Rab proteins, label specific vesicle types and mediate their targeting to the appropriate membrane (see Table 14-3). Activated Rab·GTP in a vesicle can bind to a specific type of effector protein. One type of effector

is a peripheral membrane protein complex that tethers the vesicle to the correct target membrane.

- Each v-SNARE in a vesicular membrane specifically binds to a complex of cognate t-SNARE proteins in the target membrane, inducing fusion of the two membranes. After fusion is completed, the SNARE complex is disassembled in an ATP-dependent reaction mediated by other cytosolic proteins (see Figure 14-11).

14.3 Early Stages of the Secretory Pathway

In this section, we take a closer look at vesicular traffic between the ER and the Golgi and at some of the evidence supporting the general mechanisms discussed in the previous section. Recall that anterograde transport from the ER to the Golgi, the first vesicle trafficking step in the secretory pathway, is mediated by COPII vesicles. These vesicles contain newly synthesized proteins destined for the Golgi, cell surface, or lysosomes, as well as vesicle components such as v-SNAREs that are required to target vesicles to the *cis*-Golgi membrane. Proper sorting of proteins between the ER and Golgi also requires retrograde transport from the *cis*-Golgi to the ER, which is mediated by COPI vesicles (Figure 14-12). This retrograde vesicle transport serves to retrieve v-SNARE proteins and components of the membrane itself to provide the necessary material for additional rounds of vesicle budding from the ER. COPI-mediated retrograde transport also retrieves missorted ER-resident proteins from the *cis*-Golgi.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 14-12 Vesicle-mediated protein trafficking between the ER and *cis*-Golgi. Steps 1 – 3: Forward (anterograde) transport is mediated by COPII vesicles, which are formed by polymerization of soluble COPII coat protein complexes (green) on the ER membrane. v-SNAREs (orange) and other cargo proteins (blue) in the ER membrane are incorporated into the vesicle by interacting with coat proteins. Soluble cargo proteins (magenta) are recruited

by binding to appropriate receptors in the membrane of budding vesicles. Dissociation of the coat recycles free coat complexes and exposes v-SNARE proteins on the vesicle surface. After the uncoated vesicle becomes tethered to the *cis*-Golgi membrane in a Rab-mediated process, pairing between the exposed v-SNAREs and cognate t-SNAREs in the Golgi membrane allows membrane fusion, releasing the contents of the vesicle into the *cis*-Golgi compartment (see Figure 14-10). Steps **4** – **6**: Reverse (retrograde) transport, mediated by vesicles coated with COPI proteins (purple), recycles the membrane bilayer and certain proteins, such as v-SNAREs and missorted ER-resident proteins (not shown), from the *cis*-Golgi to the ER. All SNARE proteins are shown in orange, although v-SNAREs and t-SNAREs are distinct proteins.

We also discuss in this section the process by which proteins that have been correctly delivered to the Golgi advance through successive compartments of the Golgi, from the *cis*- to the *trans*-Golgi network. This process of cisternal maturation involves budding and fusion of retrograde rather than anterograde transport vesicles.

COPII Vesicles Mediate Transport from the ER to the Golgi

COPII vesicles were first recognized when cell-free extracts of yeast rough ER membranes were incubated with cytosol and a nonhydrolyzable analog of GTP. The vesicles that formed from the ER membranes had a distinct coat similar to that on COPI vesicles, but composed of different proteins, designated *COPII proteins*. The genes encoding COPII proteins were identified by the analysis of

yeast cells with class B *sec* mutations that accumulate proteins in the rough ER (see Figure 14-5).

As described previously, formation of COPII vesicles is triggered when Sec12, a GEF in the ER membrane, catalyzes the exchange of bound GDP for GTP on cytosolic Sar1. This exchange induces binding of Sar1 to the ER membrane, followed by binding of a complex of Sec23 and Sec24 proteins (see Figure 14-9). The resulting ternary complex formed between Sar1·GTP, Sec23, and Sec24 is shown in Figure 14-13. This core coat protein complex then provides binding sites for the recruitment of a second complex of Sec13 and Sec31 proteins to complete the coat structure. Since pure Sec13 and Sec31 proteins can spontaneously assemble into cagelike lattices, it is thought that Sec13 and Sec31 form the structural scaffold for COPII vesicles (see the COPII vesicle model in the chapter opener figure). Finally, a large fibrous protein called *Sec16*, which is bound to the cytosolic surface of the ER, interacts with Sar1·GTP and the Sec13/31 and Sec23/24 complexes to organize the other coat proteins, increasing the efficiency of coat polymerization.

FIGURE 14-13 Three-dimensional structure of the ternary complex comprising the COPII coat proteins Sec23, Sec24, and Sar1·GTP. Early in the formation of the COPII coat, Sec23 (orange)/Sec24 (green) complexes are recruited to the ER membrane by Sar1 (red) in its GTP-bound state. A cargo protein in the ER membrane can be recruited to COPII vesicles by the interaction of a tripeptide di-acidic sorting signal (purple) in the cargo protein's cytosolic domain with Sec24. The likely positions of the COPII vesicle membrane and the transmembrane segment of the cargo protein are indicated. The N-terminal segment of Sar1 that tethers it to the membrane is not shown.

[Republished with permission from *Nature*, from X. Bi et al., 2002, "Structure of the Sec23/24-Sar1 Prebudding Complex of the COPII Vesicle Coat," *Nature* **419**(6904):271–277; permission conveyed through the Copyright Clearance Center, Inc.]

Certain integral ER membrane proteins are specifically recruited into COPII vesicles for transport to the Golgi. The cytosolic segments

of many of these proteins contain a *di-acidic sorting signal* (the key residues in this sequence are Asp-X-Glu, or DXE in the one-letter code) (see Table 14-2). This sorting signal, which binds to the Sec24 subunit of the COPII coat, is essential for the selective export of certain membrane proteins from the ER (see Figure 14-12). Biochemical and genetic studies have identified additional signals that help direct membrane cargo proteins into COPII vesicles. All of the known sorting signals bind to one or another site on the Sec24 subunit of COPII. Ongoing studies seek to determine how soluble cargo proteins are selectively loaded into COPII vesicles.

The inherited disease cystic fibrosis is characterized by an imbalance in chloride and sodium ion transport in the epithelial cells of the lungs, leading to fluid buildup and difficulty breathing. Cystic fibrosis is caused by mutations in a protein known as *CFTR*, which is synthesized as an integral membrane protein in the ER and is transported to the Golgi before being transported to the plasma membranes of epithelial cells, where it functions as a chloride channel. Researchers have recently shown that the CFTR protein contains a di-acidic sorting signal that binds to the Sec24 subunit of the COPII vesicle coat and is necessary for transport of the CFTR protein out of the ER. The most common CFTR mutation is a deletion of a phenylalanine at position 508 in the protein sequence (known as $\Delta F508$). This mutation prevents normal transport of CFTR to the plasma membrane by blocking its packaging into COPII vesicles budding from the ER. While the CFTR protein with the

ΔF508 mutation triggers the ER quality-control machinery, a folded CFTR with this mutation can still function properly as a normal chloride channel. However, it never reaches the membrane; the disease state is therefore caused by the absence of the channel, rather than by a defective channel. ■

COPI Vesicles Mediate Retrograde Transport Within the Golgi and from the Golgi to the ER

COPI vesicles were first discovered when isolated Golgi fractions were incubated in a solution containing cytosol and a nonhydrolyzable analog of GTP (see Figure 14-10). Subsequent analysis of these vesicles showed that the coat is formed from large cytosolic complexes, called *coatomers*, composed of seven polypeptide subunits. Yeast cells containing temperature-sensitive mutations in COPI proteins accumulate proteins in the rough ER at the nonpermissive temperature and thus are categorized as class B *sec* mutants (see Figure 14-5). Although the discovery of these mutants initially suggested that COPI vesicles mediate ER-to-Golgi transport, subsequent experiments showed that their main function is retrograde transport, both between Golgi cisternae and from the *cis*-Golgi to the rough ER (see Figure 14-12, *right*). Because COPI mutants cannot recycle key membrane proteins back to the rough ER, the ER gradually becomes depleted of ER proteins, such as v-

SNAREs, that are necessary for COPII vesicle function. Eventually, vesicle formation from the rough ER grinds to a halt; secretory proteins continue to be synthesized but accumulate in the ER — the defining characteristic of class B *sec* mutants. The general ability of *sec* mutations involved in either COPI or COPII vesicle function to eventually block both anterograde and retrograde transport illustrates the fundamental interdependence of these two transport processes.

As discussed in Chapter 13, the ER contains several soluble proteins dedicated to the folding and modification of newly synthesized secretory proteins. They include the chaperone BiP and the enzyme protein disulfide isomerase, which are necessary for the ER to carry out its functions. Although such ER-resident luminal proteins are not specifically selected by COPII vesicles, their sheer abundance causes them to be continuously loaded passively into vesicles destined for the *cis*-Golgi. The transport of these soluble proteins back to the ER, mediated by COPI vesicles, prevents their eventual depletion.

Most soluble ER-resident proteins carry a Lys-Asp-Glu-Leu (KDEL in the one-letter code) sequence at their C-terminus (see Table 14-2). Several experiments have demonstrated that this *KDEL sorting signal* is both necessary and sufficient to cause a protein bearing this sequence to be located in the ER. For instance, when a mutant protein disulfide isomerase lacking these four residues is

synthesized in cultured fibroblasts, the protein is secreted. Moreover, if a protein that is normally secreted is altered so that it contains the KDEL sorting signal at its C-terminus, the protein is located in the ER. The KDEL sorting signal is recognized and bound by the *KDEL receptor*, a transmembrane protein found primarily on small transport vesicles shuttling between the ER and the *cis*-Golgi and on the *cis*-Golgi membrane. In addition, soluble ER-resident proteins that carry the KDEL signal have oligosaccharide chains bearing modifications that are catalyzed by enzymes found only in the *cis*-Golgi or *cis*-Golgi network; thus at some time these proteins must have left the ER and been transported at least as far as the *cis*-Golgi network. These findings indicate that the KDEL receptor acts mainly to retrieve soluble proteins containing the KDEL sorting signal that have escaped to the *cis*-Golgi network and return them to the ER (Figure 14-14). The KDEL receptor binds more tightly to its ligand at low pH, and it is thought that the receptor is able to bind KDEL peptides in the *cis*-Golgi and release these peptides in the ER because the pH of the Golgi is slightly lower than that of the ER.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 14-14 Role of the KDEL receptor in retrieval of ER-resident luminal proteins from the Golgi. ER luminal proteins, especially those present at high concentrations, can be passively incorporated into COPII vesicles and transported to the Golgi (steps 1 and 2). Many such proteins bear a C-terminal KDEL (Lys-Asp-Glu-Leu) sequence (red) that allows them to be retrieved. The KDEL receptor, located mainly in the *cis*-Golgi network and in both COPII and COPI vesicles, binds proteins bearing the KDEL sorting signal and returns them to the ER (steps 3 and 4). This retrieval system prevents

depletion of ER luminal proteins such as those needed for proper folding of newly made secretory proteins. The binding affinity of the KDEL receptor is very sensitive to pH. The small difference between the pH of the ER and that of the Golgi favors binding of KDEL-bearing proteins to the receptor in Golgi-derived vesicles and their release in the ER. See J. Semenza et al., 1990, *Cell* **61**:1349.

The KDEL receptor and other membrane proteins that are transported back to the ER from the Golgi contain a Lys-Lys-X-X sequence at the very end of their C-terminal segment, which faces the cytosol (see Table 14-2). This *KKXX sorting signal*, which binds to a complex of the COPI α and β subunits (two of the seven polypeptide subunits in the COPI coatomer), is both necessary and sufficient to incorporate membrane proteins into COPI vesicles for retrograde transport to the ER. Temperature-sensitive yeast mutants lacking COPIα or COPIβ are not only unable to bind the KKXX signal, but are also unable to transport proteins bearing this signal back to the ER, indicating that COPI vesicles mediate retrograde Golgi-to-ER transport.

A second sorting signal that targets proteins to COPI vesicles and thus enables recycling from the Golgi to the ER is a di-arginine sequence. Unlike the KKXX sorting signal, which must be located at the cytoplasmically oriented C-terminus of a protein, the di-arginine sorting signal can reside in any segment of a membrane protein that is on the cytoplasmic face of the membrane.

The partitioning of proteins between the ER and Golgi complex is a highly dynamic process depending on both COPII (anterograde) and COPI (retrograde) vesicles, with each type of vesicle responsible for recycling the components necessary for the function of the other type of vesicle. The organization of this partitioning process raises an interesting puzzle: How do vesicles preferentially use the v-SNAREs that specify fusion with the correct target membrane instead of the v-SNAREs that are being recycled and specify fusion with the donor membrane?

This basic question concerning correct membrane partitioning has recently been answered for COPII vesicles. After these vesicles form, the COPII coat proteins remain assembled long enough for the Sec23/Sec24 complex to interact with a specific tethering factor attached to the *cis*-Golgi membrane. Vesicle uncoating to expose the v-SNAREs is completed only after the COPII vesicle is already closely associated with the *cis*-Golgi membrane and the COPII v-SNAREs are in position to form complexes with their cognate t-SNAREs. Although COPII vesicles also carry COPI-specific v-SNARE proteins, which are being recycled back to the *cis*-Golgi, these COPI v-SNARE proteins never have the opportunity to form SNARE complexes with cognate ER-localized t-SNARE proteins.

Anterograde Transport Through the Golgi Occurs by Cisternal Maturation

The Golgi complex is organized into three compartments, often arranged in a stacked set of flattened sacs, called *cisternae*. The compartments of the Golgi differ from one another according to the enzymes they contain. Many of the enzymes are glycosidases and glycosyltransferases that are involved in modifying the *N*-linked or *O*-linked carbohydrates attached to secretory proteins as they transit through the Golgi complex. On the whole, the Golgi complex operates much like an assembly line, where each compartment serves as an assembly station in which the carbohydrate chains modified in the previous compartment are substrates for the modifying enzymes of the next compartment. (Figure 14-15 shows a representative sequence of modification steps.)

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 14-15 Processing of *N*-linked oligosaccharide chains on glycoproteins within *cis*-, *medial*-, and *trans*-Golgi cisternae in vertebrate cells. After removal of three mannose residues in the *cis*-Golgi (step 1), the protein

moves by cisternal maturation to the *medial*-Golgi. Here three *N*-acetylglucosamine (GlcNAc) residues are added (steps 2 and 4), two more mannose residues are removed (step 3), and a single fucose is added (step 5). Processing is completed in the *trans*-Golgi by addition of three galactose residues (step 6) and finally by linkage of an *N*-acetylneuraminic acid residue to each of the galactose residues (step 7). Specific transferase enzymes add sugars to the oligosaccharide, one at a time, from sugar nucleotide precursors imported from the cytosol. The enzymes catalyzing each step are localized to the indicated compartments. This pathway represents the Golgi processing events for a typical mammalian glycoprotein. Variations in the structure of *N*-linked oligosaccharides can result from differences in processing steps in the Golgi. See R. Kornfeld and S. Kornfeld, 1985, *Annu. Rev. Biochem.* **45**:631.

For many years, it was thought that the Golgi complex was an essentially static set of compartments with small transport vesicles carrying secretory proteins forward, from the *cis*- to the *medial*-Golgi and from the *medial*- to the *trans*-Golgi. Indeed, electron microscopy reveals many small vesicles associated with the Golgi complex that appear to move proteins from one Golgi compartment to another (Figure 14-16). However, electron microscopy only provides an image of structures that is frozen in time and cannot show the direction of movement of the transport vesicles. We now know that the small vesicles in the vicinity of the Golgi complex are actually moving in the retrograde direction, retrieving ER or Golgi enzymes from a later compartment and transporting them to an earlier compartment in the secretory pathway. Thus the Golgi appears to have a highly dynamic organization, continually forming transport vesicles, though only in the retrograde direction. To see the effect of this retrograde transport on the organization of the Golgi, consider

the net effect on the *medial*-Golgi compartment as enzymes from the *trans*-Golgi move to the *medial*-Golgi while enzymes from the *medial*-Golgi are transported to the *cis*-Golgi. As this process continues, the *medial*-Golgi acquires enzymes from the *trans*-Golgi while losing *medial*-Golgi enzymes to the *cis*-Golgi and thus progressively becomes a new *trans*-Golgi compartment. In this way, secretory cargo proteins acquire carbohydrate modifications in the proper sequential order without being moved from one cisterna to another via anterograde vesicle transport.

EXPERIMENTAL FIGURE 14-16 Anterograde-moving COPII transport vesicles and retrograde-moving COPI transport vesicles are difficult to distinguish in an electron micrograph of the Golgi complex in a pancreatic acinar cell.

Elements of the rough ER are on the bottom and left in this micrograph. Adjacent to the rough ER are transitional elements from which smooth protrusions appear to be budding. These buds form the small COPII vesicles that transport secretory proteins in the anterograde direction from the rough ER to the Golgi complex. Interspersed among the Golgi cisternae are other small vesicles that are similar in appearance to the COPII vesicles, but these transport vesicles, which bear COPI coats, are now known to carry resident Golgi enzymes between Golgi compartments in the retrograde direction. A large anterograde secretory vesicle can be seen forming from the *trans*-Golgi network.

The first evidence that the forward transport of cargo proteins from the *cis*- to the *trans*-Golgi occurs by this progressive mechanism of cisternal maturation came from careful microscopic analysis of the synthesis of large macromolecular complexes that follow the secretory pathway to form scales on the surface of certain types of unicellular algae. These algal scales are assembled from glycoproteins in the *cis*-Golgi into large dense complexes visible in the electron microscope. Like other secretory proteins, newly made scales move from the *cis*- to the *trans*-Golgi, but they were never observed in the transport vesicles that bud from Golgi cisternae. In further experiments, the observation that the movement of large cargo molecules through the Golgi can occur without entry of cargo into transport vesicles was shown also to be true of collagen synthesized in animal cells. In fibroblasts, large aggregates of the procollagen precursor often form in the lumen of the *cis*-Golgi. The procollagen aggregates are too large to be incorporated into small transport vesicles, and investigators could never find such

aggregates in transport vesicles. These observations show that the forward movement of these, and perhaps all, secretory proteins from one Golgi compartment to another does *not* occur via small vesicles.

A particularly elegant demonstration of cisternal maturation in yeast takes advantage of different-colored fluorescent labels to image two different Golgi proteins simultaneously. Figure 14-17 shows how a *cis*-Golgi resident protein labeled with a green fluorescent protein and a *trans*-Golgi resident protein labeled with a red fluorescent protein behave in the same yeast cell. At any given moment, individual Golgi cisternae appear to have a distinct compartmental identity, in the sense that they contain either the *cis*-Golgi protein or the *trans*-Golgi protein, but only rarely contain both proteins. However, over time, an individual cisterna labeled with the *cis*-Golgi protein can be seen to progressively lose this protein and acquire the *trans*-Golgi protein. This behavior is exactly that predicted by the cisternal maturation model, in which the composition of an individual cisterna changes as Golgi resident proteins move from later to earlier Golgi compartments.

EXPERIMENTAL FIGURE 14-17 Fluorescence-tagged fusion proteins demonstrate Golgi cisternal maturation in a live yeast cell. Yeast cells expressing the early Golgi protein Vrg4 fused to GFP (green fluorescence) and the late Golgi protein Sec7 fused to DsRed (red fluorescence) were imaged by time-lapse microscopy. The top series of images, taken approximately 1 minute apart, shows a collection of Golgi cisternae, which at any one time are labeled with either Vrg4 or Sec7. The bottom series of images are digitally processed to show just the Golgi cisterna, identified by the white arrows in the top set of images. At first, only Vrg4-GFP is located in the isolated cisterna, and later only Sec7-DsRed is located in the isolated cisterna, following a brief period in which both proteins are co-localized in this compartment. This experiment is a direct demonstration of the cisternal maturation hypothesis, showing that the composition of individual cisternae follows a process of maturation characterized by loss of early Golgi proteins and gain of late Golgi proteins.

[Republished with permission from *Nature*, from E. Losev et al., 2006, "Golgi Maturation Visualized in Living Yeast," *Nature* **441**:1002–1006; permission conveyed through Copyright Clearance Center, Inc.]

Although most protein traffic moves through the Golgi complex by a cisternal maturation mechanism, there is evidence that at least some cargo proteins can be detected in COPI transport vesicles that bud from Golgi membranes. This observation suggests that there may be a subset of COPI transport vesicles that move cargo in an anterograde direction.

KEY CONCEPTS OF SECTION 14.3

Early Stages of the Secretory Pathway

- COPII vesicles transport proteins from the rough ER to the *cis*-Golgi; COPI vesicles transport proteins in the reverse direction (see Figure 14-12).
- COPII coats comprise three major components: the small GTP-binding protein Sar1, a Sec23/Sec24 complex, and a Sec13/Sec31 complex.
- Components of the COPII coat bind to membrane cargo proteins containing a di-acidic or other sorting signal in their cytosolic regions (see Figure 14-13). Soluble cargo proteins are probably targeted to COPII vesicles by binding to a membrane protein receptor.
- Many soluble ER-resident proteins contain a KDEL sorting signal. Binding of this retrieval sequence to a specific receptor protein in the *cis*-Golgi membrane recruits missorted ER proteins into retrograde COPI vesicles (see Figure 14-14).
- Membrane proteins needed to form COPII vesicles can be retrieved from the *cis*-Golgi by COPI vesicles. One of the sorting signals that directs membrane proteins into COPI vesicles is a KKXX sequence, which binds to subunits of the COPI coat. A distinct di-arginine sorting signal operates by a similar mechanism.
- COPI vesicles also carry Golgi-resident proteins from later to earlier compartments in the Golgi complex.
- Soluble and membrane proteins advance through the Golgi complex by cisternal maturation, a process of anterograde transport that depends on resident Golgi enzymes moving by COPI vesicular transport in a retrograde direction.

14.4 Later Stages of the Secretory Pathway

As cargo proteins move from the *cis*- to the *trans*-Golgi by cisternal maturation, modifications to their oligosaccharide chains are carried out by Golgi-resident enzymes. The retrograde trafficking of COPI vesicles from later to earlier Golgi compartments maintains sufficient levels of these carbohydrate-modifying enzymes in the appropriate compartments. Eventually, properly processed cargo proteins reach the *trans*-Golgi network, the most distal Golgi compartment. Here they are sorted into a number of different kinds of vesicles for delivery to their final destination. Each of the target destinations, such as the plasma membrane, endosomes, and lysosomes, has a unique composition of lipids and membrane proteins, and it is primarily the sorting in the *trans*-Golgi network that gives each of these organelles its unique identity. In this section, we discuss the different kinds of vesicles that bud from the *trans*-Golgi network, the mechanisms that segregate cargo proteins among them, and key processing events that occur late in the secretory pathway. The various types of vesicles that bud from the *trans*-Golgi and will be described in this section are summarized in Figure 14-18.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 14-18 Vesicle-mediated protein trafficking from the *trans*-Golgi network. COPI (purple) vesicles mediate retrograde transport within the Golgi (1). Proteins that function in the lumen or in the membrane of the lysosome are first transported from the *trans*-Golgi network via AP complex and clathrin-coated (red) vesicles (2); after uncoating, these vesicles fuse with late endosomes, which deliver their contents to the lysosome. Some vesicles from the *trans*-Golgi carrying cargo destined for the lysosome fuse with the lysosome directly (3), bypassing the late endosome. These vesicles are coated with AP3 complex (blue); it is unknown whether these vesicles also contain clathrin. The coat proteins surrounding constitutive (4) and regulated (5) secretory vesicles have not yet been characterized; these vesicles carry secreted proteins and plasma-membrane proteins from the *trans*-Golgi network to the cell surface.

Vesicles Coated with Clathrin and Adapter Proteins Mediate Transport from the *trans*-Golgi

The best characterized vesicles that bud from the *trans*-Golgi network have a two-layered coat: an outer layer composed of the fibrous protein clathrin and an inner layer composed of **adapter protein (AP) complexes**. Purified clathrin molecules, which have a three-limbed shape, are called *triskelions*, from the Greek for "three-legged" (Figure 14-19a). Each limb contains one clathrin heavy chain (180 kDa) and one clathrin light chain (~35–40 kDa). Triskelions polymerize to form a polygonal lattice with an intrinsic curvature (Figure 14-19b). When clathrin polymerizes on a donor membrane, it does so in association with AP complexes, which fill the space between the clathrin lattice and the membrane. Each AP complex (340 kDa) contains one copy each of four different adapter subunit proteins. A specific association between the globular domain at the end of each clathrin heavy chain in a triskelion and one subunit of the AP complex both promotes the co-assembly of clathrin triskelions with AP complexes and adds to the stability of the completed vesicle coat.

FIGURE 14-19 Structure of clathrin coats. (a) A clathrin molecule, called a *triskelion*, is composed of three heavy and three light chains. It has an intrinsic curvature due to the bend in the heavy chains. (b) Clathrin coats were formed in vitro by mixing purified clathrin heavy and light chains with AP2 complexes in the absence of membranes. Cryoelectron micrographs of more than 1000 assembled hexagonal clathrin barrel particles were analyzed by digital image processing to generate an average structural representation. The processed image shows only the clathrin heavy chains in a structure composed of 36 triskelions. Three representative triskelions are highlighted in red, yellow, and green. Some of the AP2 complexes packed into the interior of the clathrin cage are also visible in this representation. See B. Pishvaee and G. Payne, 1998, *Cell* **95**:443.

[Part (b) Republished with permission from *Nature*, from A. Fotin et al., 2004, "Molecular Model for a Complete Clathrin Lattice from Electron Cryomicroscopy," *Nature* **432**:573–579; permission conveyed through Copyright Clearance Center, Inc.]

Adapter proteins determine which cargo proteins are specifically included in a budding transport vesicle by binding to the cytosolic

face of membrane proteins. Thus each of the multiple adapter protein complexes that operate in the late secretory pathway can be classified based on the types of cargo proteins that they select as well as the specific transport step that they mediate (see Table 14-1). Three different AP complexes are known (AP1, AP2, and AP3), each with four subunits of different, though related, proteins. A second general type of adapter protein, known as *GGA*, consists of a single 70 kDa polypeptide. This monomeric adapter protein has been shown to contain both clathrin- and cargo-binding elements similar to those found in the much larger hetero-tetrameric AP complexes. All vesicles whose coats contain one of these complexes use ARF to initiate coat assembly on the donor membrane. As discussed previously, ARF also initiates assembly of COPI coats. The additional membrane features or protein factors that determine which type of coat will assemble after ARF attachment are not well understood at this time.

Vesicles that bud from the *trans*-Golgi network en route to the lysosome by way of the late endosome (see Figure 14-18, **3**) have clathrin coats associated with either AP1 or GGA. One of the AP1 subunits in the vesicle coat binds to membrane proteins containing a Tyr-X-X-Φ sequence. Proteins bearing this *YXXΦ sorting signal* are recruited into clathrin/AP1-coated vesicles budding from the *trans*-Golgi network. As we discuss in the next section, vesicles with clathrin/AP2 coats, which bud from the plasma membrane during endocytosis, can also recognize the YXXΦ sorting signal. Vesicles

coated with GGA proteins and clathrin bind cargo molecules with different kinds of sorting sequences including Asp-X-Leu-Leu and Asp-Phe-Gly-X-Φ sequences.

Some vesicles that bud from the *trans*-Golgi network have coats composed of the AP3 complex. Although the AP3 complex does contain a binding site for clathrin similar to those in the AP1 and AP2 complexes, it is not clear whether clathrin is necessary for the functioning of AP3-containing vesicles because mutant versions of AP3 that lack the clathrin binding site appear to be fully functional. AP3-coated vesicles mediate trafficking to the lysosome, but they appear to bypass the late endosome and fuse directly with the lysosomal membrane (see Figure 14-18, **2**). In certain types of cells, such AP3 vesicles mediate protein transport to specialized storage compartments related to the lysosome. For example, AP3 is required for delivery of proteins to melanosomes, which contain the black pigment melanin in skin cells, and to platelet storage vesicles in megakaryocytes, large cells that fragment into dozens of platelets. Mice with mutations in either of two different subunits of AP3 not only have abnormal skin pigmentation but also exhibit bleeding disorders. The latter occur because platelets require normal storage vesicles in order to repair tears in blood vessels.

Dynamin Is Required for Pinching Off of Clathrin-Coated Vesicles

A fundamental step in the formation of a transport vesicle that we have not yet considered is how a vesicle bud is pinched off from the donor membrane. In the case of clathrin-coated vesicles, a cytosolic protein called **dynamin** is essential for the release of complete vesicles. At the later stages of bud formation, dynamin polymerizes around the neck portion of the bud and then hydrolyzes GTP. The energy derived from GTP hydrolysis is thought to drive a conformational change in dynamin that stretches the neck until the vesicle pinches off (Figure 14-20).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 14-20 Model for dynamin-mediated pinching off of clathrin-coated vesicles. After a vesicle bud forms, dynamin polymerizes over the neck. By a mechanism that is not well understood, dynamin-catalyzed hydrolysis of GTP leads to release of the vesicle from the donor membrane. Note that membrane proteins in the donor membrane are incorporated into vesicles by interacting with AP complexes in the coat. See K. Takel et al., 1995, *Nature* **374**:186.

Incubation of cell extracts with a nonhydrolyzable derivative of GTP provides dramatic evidence for the importance of dynamin in the pinching off of clathrin/AP2-coated vesicles during endocytosis. Such treatment leads to accumulation of clathrin-coated vesicle buds with excessively long necks that are surrounded by polymeric dynamin but do not pinch off (Figure 14-21). Likewise, cells expressing mutant forms of dynamin that cannot bind GTP do not form clathrin-coated vesicles and instead accumulate similar long-necked vesicle buds encased with polymerized dynamin.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 14-21 GTP hydrolysis by dynamin is required for the pinching off of clathrin-coated vesicles in cell-free extracts. A preparation of nerve terminals, which undergo extensive endocytosis, was lysed by treatment with distilled water and incubated with GTP-γ-S, a nonhydrolyzable derivative of GTP. After sectioning, the preparation was treated with gold-tagged anti-dynamin antibody and viewed in the electron microscope. This image, which shows a long-necked clathrin/AP-coated bud with polymerized dynamin lining

the neck, reveals that buds can form in the absence of GTP hydrolysis, but vesicles cannot pinch off. The extensive polymerization of dynamin that occurs in the presence of GTP-γ-S probably does not occur during the normal budding process.

[Republished by permission from *Nature*, from K. Takei et al., 1995, "Tubular Membrane Invaginations Coated by Dynamin Rings Are Induced by GTP-Gamma S in Nerve Terminals," *Nature* **374**:(6518):186–190; permission conveyed through Copyright Clearance Center, Inc.]

Like COPI and COPII vesicles, clathrin-coated vesicles normally lose their coat soon after their formation. Cytosolic Hsp70, a constitutive chaperone protein found in all eukaryotic cells, is thought to use energy derived from the hydrolysis of ATP to drive depolymerization of the clathrin coat into triskelions. In the case of endocytic vesicles, uncoating not only releases triskelions for reuse in the formation of additional vesicles but also exposes v-SNAREs for use in fusion with target membranes. Vesicle uncoating by cytosolic Hsp70 appears to be activated by a co-chaperone, auxillin, that contains a domain that stimulates the ATP hydrolysis by Hsp70. Conformational changes that occur when ARF switches from the GTP-bound to the GDP-bound state are thought to regulate the timing of clathrin coat depolymerization, but how the action of Hsp70 and auxillin is coupled to ARF switching is not well understood.

Mannose 6-Phosphate Residues Target Resident Enzymes to Lysosomes

As we have seen, many of the sorting signals that direct cargo-protein trafficking in the secretory pathway are short amino acid sequences in the targeted protein. In contrast, the sorting signal that directs soluble lysosomal enzymes from the *trans*-Golgi network to the late endosome is a carbohydrate residue, **mannose 6-phosphate (M6P)**, which is formed in the *cis*-Golgi. The addition and initial processing of one or more preformed *N*-linked oligosaccharide precursors in the rough ER is the same for lysosomal enzymes as for membrane and secreted proteins, yielding core $Man_8(GlcNAc)_2$ chains (see Figure 13-18). In the *cis*-Golgi, the *N*-linked oligosaccharides present on most lysosomal enzymes undergo a two-step reaction sequence that generates M6P residues (Figure 14-22). The addition of M6P residues to the oligosaccharide chains of soluble lysosomal enzymes prevents these proteins from undergoing the further processing reactions characteristic of secreted and membrane proteins (see Figure 14-15).

FIGURE 14-22 Formation of mannose 6-phosphate (M6P) residues that target soluble enzymes to lysosomes. The M6P residues that direct proteins to lysosomes are generated in the *cis*-Golgi by two Golgi-resident enzymes. Step **1**: An *N*-acetylglucosamine (GlcNAc) phosphotransferase transfers a phosphorylated GlcNAc group to carbon atom 6 of one or more mannose residues. Because only lysosomal enzymes contain sequences (red) that are recognized and bound by this enzyme, phosphorylated GlcNAc groups are added specifically to lysosomal enzymes. Step **2**: After release of the modified protein from the

phosphotransferase, a phosphodiesterase removes the GlcNAc group, leaving a phosphorylated mannose residue on the lysosomal enzyme. See A. B. Cantor et al., 1992, *J. Biol. Chem.* **267**:23349; and S. Kornfeld, 1987, *FASEB J.* **1**:462.

As shown in Figure 14-23, the segregation of M6P-bearing lysosomal enzymes from secreted and membrane proteins occurs in the *trans*-Golgi network. Here transmembrane *mannose 6-phosphate receptors* bind the M6P residues on lysosome-destined proteins very tightly and specifically. Clathrin/AP1-coated vesicles containing the M6P receptor and bound lysosomal enzymes then bud from the *trans*-Golgi network, lose their coats, and subsequently fuse with a late endosome by mechanisms described previously (Figure 14-18). Because M6P receptors can bind M6P at the slightly acidic pH (~ 6.5) of the *trans*-Golgi network, but not at a pH of less than 6, the bound lysosomal enzymes are released within late endosomes, which have an internal pH of 5.0–5.5. Furthermore, a phosphatase within late endosomes usually removes the phosphate from M6P residues on lysosomal enzymes, preventing any rebinding to the M6P receptor that might occur in spite of the low pH there. Vesicles budding from late endosomes, coated with a protein complex known as the **retromer**, recycle the M6P receptor back to the *trans*-Golgi network. Eventually, mature late endosomes fuse with lysosomes, delivering the lysosomal enzymes to their final destination.

FIGURE 14-23 Trafficking of soluble lysosomal enzymes from the *trans*-Golgi network and cell surface to lysosomes. Newly synthesized lysosomal enzymes, produced in the ER, acquire mannose 6-phosphate (M6P) residues in the *cis*-Golgi (see Figure 14-22). For simplicity, only one phosphorylated oligosaccharide chain is depicted, although lysosomal enzymes typically have many such chains. In the *trans*-Golgi network, proteins that bear the M6P sorting signal interact with M6P receptors in the membrane and thereby are directed into clathrin/AP1-coated vesicles (step **1**). The coat surrounding released vesicles is rapidly depolymerized (step **2**), and the uncoated transport vesicles fuse with late endosomes (step **3**). Note that disassembled coat proteins are recycled for additional rounds of vesicle assembly (step **2a**). After the phosphorylated enzymes dissociate from the M6P receptors in late endosomes, free M6P receptors are recycled by incorporation into vesicles that bud from the late endosome (step **4**). Vesicles carrying free M6P receptors can return to the *trans*-Golgi or fuse with the plasma membrane delivering M6P receptors to

the cell surface (step 5). Phosphorylated lysosomal enzymes are also occasionally sorted from the *trans*-Golgi to the cell surface and secreted. These secreted enzymes can be retrieved by receptor-mediated endocytosis (steps 6–8). Ultimately, fusion of the late endosome with the lysosome delivers phosphorylated lysosomal enzymes to the interior of the lysosomes (step 9). See G. Griffiths et al., 1988, *Cell* **52**:329; S. Kornfeld, 1992, *Annu. Rev. Biochem.* **61**:307; and G. Griffiths and J. Gruenberg, 1991, *Trends Cell Biol.* **1**:5.

The sorting of soluble lysosomal enzymes in the *trans*-Golgi network (Figure 14-23, steps **1**–**4**) shares many features with the trafficking of proteins between the ER and *cis*-Golgi compartments mediated by COPII and COPI vesicles. First, M6P acts as a sorting signal by interacting with the luminal domain of a receptor protein in the donor membrane. Second, the membrane-embedded receptors with their bound ligands are incorporated into the appropriate vesicles — in this case, either GGA- or AP1-containing clathrin-coated vesicles — by interacting with the vesicle coat. Third, these transport vesicles fuse with only one specific organelle, here the late endosome, as the result of interactions between specific v-SNAREs and t-SNAREs. And finally, intracellular transport receptors dissociated from their bound ligand are recycled by retrograde vesicle trafficking.

Study of Lysosomal Storage Diseases Revealed Key Components of the Lysosomal Sorting Pathway

A group of genetic disorders termed *lysosomal storage diseases* are caused by the absence of one or more lysosomal enzymes. As a result, undigested glycolipids and extracellular components that would normally be degraded by lysosomal enzymes accumulate in lysosomes as large inclusions. Patients with lysosomal storage diseases can have a variety of developmental, physiological, and neurological abnormalities depending on the type and severity of the storage defect. *I-cell disease* is a particularly severe type of lysosomal storage disease in which multiple enzymes are missing from the lysosomes. Cells from affected individuals lack the *N*-acetylglucosamine phosphotransferase that is required for formation of M6P residues on lysosomal enzymes in the *cis*-Golgi (see Figure 14-22). Biochemical comparison of lysosomal enzymes from normal individuals with those from patients with I-cell disease led to the initial discovery of M6P as the lysosomal sorting signal. Lacking this signal, the lysosomal enzymes of affected individuals are secreted rather than being sorted to and sequestered in lysosomes.

When fibroblasts from patients with I-cell disease are grown in a medium containing lysosomal enzymes bearing M6P residues, the diseased cells acquire a nearly normal intracellular content of lysosomal enzymes. This finding indicates that the plasma membrane of these cells contains M6P receptors, which can internalize extracellular phosphorylated lysosomal enzymes by receptor-mediated endocytosis. This process, used by many cell-

surface receptors to bring bound proteins or particles into the cell, is discussed in detail in the next section. It is now known that even in normal cells, some M6P receptors are transported to the plasma membrane and some phosphorylated lysosomal enzymes are secreted (see Figure 14-23). The secreted enzymes can be retrieved by receptor-mediated endocytosis and directed to lysosomes. This pathway thus scavenges any lysosomal enzymes that escape the usual M6P sorting pathway.

Hepatocytes from patients with I-cell disease contain a normal complement of lysosomal enzymes and no inclusions, even in the absence of an exogeneous source of lysosomal enzymes bearing M6P residues. This finding implies that hepatocytes (the most abundant type of liver cell) employ a pathway for sorting lysosomal enzymes that does not rely on a targeting signal based on M6P. This pathway probably relies on some yet unidentified protein-based sorting signal present in lysosomal enzymes. ■

Protein Aggregation in the *trans*-Golgi May Function in Sorting Proteins to Regulated Secretory Vesicles

As noted in the chapter introduction, all eukaryotic cells continuously secrete certain proteins (constitutive secretion). Specialized secretory cells store other proteins in vesicles and

secrete them only when triggered by a specific stimulus. One example of such regulated secretion occurs in pancreatic β cells, which store newly made insulin in specialized secretory vesicles and secrete it in response to an elevation in blood glucose (see Figure 21-1b). These and other secretory cells simultaneously use two different types of secretory vesicles to move proteins from the *trans*-Golgi network to the cell surface: unregulated transport vesicles (also called *constitutive secretory vesicles*) and regulated transport vesicles.

A common mechanism appears to sort regulated proteins as diverse as ACTH (adrenocorticotropic hormone), insulin, and trypsinogen into regulated secretory vesicles. Evidence for such a common mechanism comes from experiments in which recombinant DNA techniques were used to induce the synthesis of insulin and trypsinogen in pituitary tumor cells already synthesizing ACTH. In these cells, which do not normally express insulin or trypsinogen, all three proteins segregate into the same regulated secretory vesicles and are secreted together when a hormone binds to a receptor on the pituitary cells and causes a rise in cytosolic Ca^{2+}.

Morphologic evidence suggests that the ability to form protein aggregates is a common feature of all three proteins that governs their packaging into regulated secretory vesicles. For instance, immature vesicles in this pathway — those that have just budded from the *trans*-Golgi network — contain diffuse aggregates of

secretory protein that are visible in the electron microscope. These aggregates are also found in vesicles that are in the process of budding, indicating that proteins destined for regulated secretory vesicles selectively aggregate together before their incorporation into the vesicles.

Some Proteins Undergo Proteolytic Processing After Leaving the *trans*-Golgi

For some secretory proteins (e.g., growth hormone) and certain viral membrane proteins (e.g., VSV G protein), removal of the N-terminal ER signal sequence from the nascent chain is the only known proteolytic cleavage required to convert the polypeptide to the mature, active protein (see Figure 13-10). However, some membrane proteins and many soluble secretory proteins are initially synthesized as relatively long-lived, inactive precursors, termed *proproteins*, that require further proteolytic processing to generate the mature, active proteins. Examples of proteins that undergo such processing are soluble lysosomal enzymes; many membrane proteins, such as influenza hemagglutinin (HA); and secreted proteins such as serum albumin, insulin, glucagon, and the yeast α mating factor. In general, the proteolytic conversion of a proprotein to the corresponding mature protein occurs after the

proprotein has been sorted in the *trans*-Golgi network to appropriate vesicles.

In the case of soluble lysosomal enzymes, the proproteins, called *proenzymes*, are sorted by the M6P receptor as catalytically inactive enzymes. Once in the late endosome or lysosome, a proenzyme undergoes a proteolytic cleavage that generates a smaller but enzymatically active polypeptide. Delaying the activation of lysosomal proenzymes until they reach the lysosome prevents them from digesting macromolecules in earlier compartments of the secretory pathway.

The proproteins of most constitutively secreted proteins (e.g., albumin) are cleaved only once at a site C-terminal to a dibasic recognition sequence such as Arg-Arg or Lys-Arg (Figure 14-24a). Proteolytic processing of proteins whose secretion is regulated generally entails additional cleavages. In the case of proinsulin, multiple cleavages of the single polypeptide chain yield the N-terminal B chain and the C-terminal A chain of mature insulin, which are linked by disulfide bonds, and the central C peptide, which is lost and subsequently degraded (Figure 14-24b).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 14-24 Proteolytic processing of proproteins in the constitutive and regulated secretory pathways. The processing of proalbumin and proinsulin is

typical of the constitutive and regulated pathways, respectively. The endoproteases that function in such processing cleave at the C-terminal end of a sequence of two consecutive amino acids. (a) The endoprotease furin acts on the precursors of constitutive secreted proteins. (b) Two endoproteases, PC2 and PC3, act on the precursors of regulated secreted proteins. The final processing of many such proteins is catalyzed by a carboxypeptidase that sequentially removes two basic amino acid residues at the C-terminus of a polypeptide. See D. Steiner et al., 1992, *J. Biol. Chem.* **267**:23435.

The processing cleavages are carried out by the members of a family of endoproteases located in the late secretory pathway, all of which cleave a protein chain on the C-terminal side of an Arg-Arg or Lys-Arg sequence. One, called *furin*, is found in all mammalian cells; it processes proteins such as albumin that are secreted constitutively. In contrast, the *PC2* and *PC3 endoproteases* are found only in cells that exhibit regulated secretion; these enzymes are localized to regulated secretory vesicles and proteolytically cleave the precursors of many hormones at specific sites.

Distinct Pathways Sort Membrane Proteins to the Apical or Basolateral Region of Polarized Cells

The plasma membrane of a polarized epithelial cell is divided into two domains: *apical* and *basolateral*. Tight junctions located between the two domains prevent the movement of plasma-membrane

proteins between them (see Figure 20-19). Several sorting mechanisms direct newly synthesized membrane proteins to either the apical or the basolateral domain of epithelial cells, and any one protein may be sorted by more than one mechanism. As a result of this sorting and the restriction on protein movement within the plasma membrane by tight junctions, distinct sets of proteins are found in the apical and basolateral domains. This preferential localization of certain transport proteins is critical to a variety of important physiological functions, such as absorption of nutrients from the intestinal lumen and acidification of the stomach lumen (see Figures 11-30 and 11-31).

In one mechanism, the sorting takes place in the *trans*-Golgi network. Microscopic and cell-fractionation studies indicate that proteins destined for either the apical or the basolateral membrane are initially transported together to the membranes of the *trans*-Golgi network. In some cases, proteins destined for the apical membrane are sorted into their own transport vesicles that bud from the *trans*-Golgi network and then move to the apical region, whereas proteins destined for the basolateral membrane are sorted into other vesicles that move to the basolateral region. The different vesicle types can be distinguished by their protein constituents, including distinct Rab and v-SNARE proteins, which apparently target them to the appropriate plasma-membrane domain. In this mechanism, segregation of proteins destined for the two domains

occurs as cargo proteins are incorporated into particular types of vesicles budding from the *trans*-Golgi network.

Such direct basolateral-apical sorting has been investigated in cultured Madin-Darby canine kidney (MDCK) cells, a line of cultured polarized epithelial cells (see Figure 4-4). In MDCK cells infected with the influenza virus, progeny viruses bud only from the apical membrane, whereas in cells infected with vesicular stomatitis virus, progeny viruses bud only from the basolateral membrane. This difference occurs because the HA glycoprotein of influenza virus is transported from the Golgi complex exclusively to the apical membrane and the VSV G protein is transported only to the basolateral membrane (Figure 14-25).

FIGURE 14-25 Sorting of proteins destined for the apical and basolateral plasma membranes of polarized cells. Cells that form an epithelial cell layer contain distinct apical and basolateral domains of the plasma membrane separated by tight junctions. Distinct sorting pathways in the late secretory pathway govern sorting to either the basolateral or apical membrane. **1**: In the *trans*-Golgi, one type of vesicle transports proteins such as VSV G protein and endogenous proteins that carry a basolateral targeting sequence directly to the basolateral membrane. **2**: A second type of vesicle budding from the *trans*-Golgi carries influenza HA protein and GPI-linked proteins directly to the apical membrane. **3**: Through a process known as *transcytosis*, proteins can move from the basolateral to the apical membrane. Transcytosis involves endocytosis in clathrin/AP coated vesicles from the basolateral membrane, recycling from an endocytic compartment of basolateral proteins back to the basolateral membrane, and delivery of transcytosed apical proteins to the apical membrane. See K. Simons and A. Wandinger-Ness, 1990, *Cell* **62**:207; and K. Mostov et al., 1992, *J. Cell Biol.* **116**:577.

Mutational studies on proteins, such as the VSV G protein, that are specifically targeted to the basolateral domain have defined Tyr-X-X-Φ and Asp-X-Leu-Leu sorting signals. As we have seen, proteins bearing these motifs are recruited into clathrin/AP-coated vesicles, strongly implicating clathrin-coated vesicles in the sorting of proteins to the basolateral membrane.

Among the cellular proteins that undergo similar apical-basolateral sorting in the Golgi are those with a *glycosylphosphatidylinositol (GPI) membrane anchor*. In MDCK cells and most other types of epithelial cells, GPI-anchored proteins are targeted to the apical membrane. In membranes, GPI-anchored proteins are clustered into lipid rafts, which are rich in sphingolipids (see Chapter 10). This finding suggests that lipid rafts are localized to the apical membrane along with proteins that preferentially partition them in many cells. However, the GPI anchor is not an apical sorting signal in all polarized cells; in thyroid cells, for example, GPI-anchored proteins are targeted to the basolateral membrane. Other than GPI anchors, no unique sequences have been identified that are both necessary and sufficient to target proteins to either the apical or basolateral domain. Instead, each membrane protein may contain multiple sorting signals, any one of which can target it to the appropriate plasma-membrane domain. The identities of these complex signals and of the vesicle coat proteins that recognize them are currently

being pursued for a number of different proteins that are sorted to specific plasma-membrane domains of polarized epithelial cells.

Another mechanism for sorting apical and basolateral proteins, also illustrated in Figure 14-25, operates in hepatocytes. The basolateral membranes of hepatocytes face the blood (like those of intestinal epithelial cells), and the apical membranes line the small intercellular channels into which bile is secreted. In hepatocytes, newly made apical and basolateral proteins are first transported in vesicles from the *trans*-Golgi network to the basolateral region and incorporated into the plasma membrane by exocytosis (i.e., fusion of the vesicle membrane with the plasma membrane). From there both basolateral and apical proteins are endocytosed in the same vesicles, but then their paths diverge. The endocytosed basolateral proteins are sorted into transport vesicles that recycle them to the basolateral membrane. In contrast, the apically destined endocytosed proteins are sorted into transport vesicles that move across the cell and fuse with the apical membrane, a process called **transcytosis**. This process is also used to move extracellular materials from one side of an epithelium to another. Even in epithelial cells, such as MDCK cells, in which apical-basolateral protein sorting occurs in the Golgi, transcytosis may provide an editing function by which an apical protein sorted incorrectly to the basolateral membrane is subjected to endocytosis and then correctly delivered to the apical membrane.

KEY CONCEPTS OF SECTION 14.4

Later Stages of the Secretory Pathway

- The *trans*-Golgi network is a major branch point in the secretory pathway where soluble secreted proteins, lysosomal proteins, and in some cells, membrane proteins destined for the basolateral or apical plasma membrane are segregated into different transport vesicles.
- Many vesicles that bud from the *trans*-Golgi network as well as endocytic vesicles bear a coat composed of AP (adapter protein) complexes and clathrin (see Figure 14-19).
- The pinching off of clathrin-coated vesicles requires dynamin, which forms a collar around the neck of the vesicle bud and hydrolyzes GTP (see Figure 14-20).
- Soluble enzymes destined for lysosomes are modified in the *cis*-Golgi by the addition of multiple mannose 6-phosphate (M6P) residues to their oligosaccharide chains.
- M6P receptors in the membrane of the *trans*-Golgi network bind proteins bearing M6P residues and direct them to late endosomes, where receptors and their ligand proteins dissociate. The receptors are then recycled to the Golgi or plasma membrane, and the lysosomal enzymes are delivered to lysosomes (see Figure 14-23).
- Regulated secreted proteins are concentrated and stored in secretory vesicles to await a neuronal or hormonal signal for exocytosis. Protein aggregation within the *trans*-Golgi network may play a role in sorting secreted proteins to the regulated secretory pathway.
- Many proproteins transported through the secretory pathway undergo post-Golgi proteolytic cleavages that yield the mature, active proteins. This proteolytic maturation can occur in vesicles carrying proteins from the *trans*-Golgi network to the cell surface, in the late endosome, or in the lysosome.
- In polarized epithelial cells, membrane proteins destined for the apical and basolateral domains of the plasma membrane are sorted in the *trans*-Golgi network into different transport vesicles (see Figure 14-25). Tyr-X-X-Φ and Asp-X-Leu-Leu sorting signals target proteins to the basolateral membrane, whereas a GPI anchor targets proteins to the apical membrane.
- In hepatocytes and some other polarized cells, all plasma-membrane proteins are directed first to the basolateral membrane. Apically destined proteins are then endocytosed and moved across the cell to the apical membrane (transcytosis).

14.5 Receptor-Mediated Endocytosis

In previous sections, we have explored the main pathways of vesicle trafficking responsible for delivering soluble and membrane secretory proteins synthesized on the rough ER to the cell surface. The same basic principle of coated vesicle budding and fusion are responsible for the ability of animal cells to internalize macromolecules from their surroundings and to deliver these macromolecules to particular intracellular destinations. In this process, known as **receptor-mediated endocytosis**, a specific receptor on the cell surface binds tightly to an extracellular macromolecular ligand that it recognizes; then the complex of receptor and ligand are recruited to a plasma-membrane region that buds inward to form a coated transport vesicle. Plant cells and fungal cells take up small molecules by endocytosis, but generally do not take up macromolecules, which cannot readily pass through the cell wall because of their size.

Among the common macromolecules that vertebrate cells internalize by receptor-mediated endocytosis are cholesterol-containing low-density lipoprotein (LDL) particles, the iron-carrying protein transferrin, many protein hormones (e.g., insulin), and certain glycoproteins. Receptor-mediated endocytosis of such ligands generally occurs via clathrin/AP2-coated pits and vesicles in a process similar to the packaging of lysosomal enzymes by the

binding of M6P in the *trans*-Golgi network (see Figure 14-23). As noted earlier, some M6P receptors are found on the cell surface, and these receptors participate in the receptor-mediated endocytosis of lysosomal enzymes that are mistakenly secreted. In general, the transmembrane receptor proteins that function in the uptake of extracellular ligands are internalized from the cell surface during endocytosis and are then sorted and recycled back to the cell surface, much as M6P receptors are recycled to the plasma membrane and *trans*-Golgi. The rate at which a ligand is internalized is limited by the amount of its corresponding receptor on the cell surface.

Clathrin/AP2-coated pits make up about 2 percent of the surface of cells such as hepatocytes and fibroblasts. Many internalized ligands have been observed in clathrin/AP2-coated pits and vesicles, which are thought to function as intermediates in the endocytosis of most (though not all) ligands bound to cell-surface receptors (Figure 14-26). Some receptors are clustered over clathrin-coated pits even in the absence of ligand. Other receptors diffuse freely in the plane of the plasma membrane but undergo a conformational change when they bind to ligand, so that when the receptor-ligand complex diffuses into a clathrin-coated pit, it is retained there. Two or more types of receptor-bound ligands, such as LDL and transferrin, can be seen in the same coated pit or vesicle.

EXPERIMENTAL FIGURE 14-26 The initial stages of receptor-mediated endocytosis of low-density lipoprotein (LDL) particles are revealed by electron microscopy. Cultured human fibroblasts were incubated in a medium containing LDL particles covalently linked to the electron-dense, iron-containing protein ferritin; each small iron particle in ferritin is visible as a small dot under the electron microscope. Cells were initially incubated at 4 °C; at this temperature LDL can bind to its receptor, but internalization does not occur. After excess LDL not bound to the cells was washed away, the cells were warmed to 37 °C and then prepared for microscopy at periodic intervals. (a) A coated pit, showing the clathrin coat on the inner (cytosolic) surface of the pit, soon after the temperature was raised. (b) A pit containing LDL, apparently closing on itself to form a coated vesicle. (c) A coated vesicle containing ferritin-tagged LDL particles. (d) Ferritin-tagged LDL particles in a smooth-surfaced

early endosome, 6 minutes after internalization began. See M. S. Brown and J. Goldstein, 1986, *Science* **232**:34.

Cells Take Up Lipids from the Blood in the Form of Large, Well-Defined Lipoprotein Complexes

Lipids absorbed from the diet in the intestines or stored in adipose tissue can be distributed to cells throughout the body. To facilitate the mass transfer of lipids between cells, animals have evolved an efficient way to package hundreds or even thousands of lipid molecules into water-soluble, macromolecular carriers, called *lipoproteins*, which cells can take up from the circulation as an ensemble. A lipoprotein particle has a shell composed of proteins (*apolipoproteins*) overlying a cholesterol-containing phospholipid monolayer. The shell is amphipathic because its outer surface is hydrophilic, making the particle water soluble, and its inner surface is hydrophobic. Beneath the hydrophobic inner surface of the shell is a core of neutral lipids containing mostly cholesteryl esters, triglycerides, or both. Mammalian lipoproteins fall into different classes, defined by their differing buoyant densities. The class we will consider here is **low-density lipoprotein (LDL)**. A typical LDL

particle, depicted in Figure 14-27, is a sphere 20–25 nm in diameter. The amphipathic outer shell is composed of a phospholipid monolayer and a single molecule of a large protein known as *apoB-100*; the core of the particle is packed with cholesterol in the form of cholesteryl esters.

FIGURE 14-27 Model of low-density lipoprotein (LDL). All classes of lipoproteins have the same general structure: an amphipathic shell composed of apolipoprotein, a phospholipid monolayer (not bilayer), and cholesterol, and a hydrophobic core composed mostly of cholesteryl esters or triglycerides, or both, but with minor amounts of other neutral lipids (e.g., some vitamins). This model of LDL is based on electron microscopy and other low-resolution biophysical methods. LDL is unique in that it contains only a single molecule of one type of apolipoprotein (ApoB), which appears to wrap around the outside of the particle as a band of protein. The other lipoproteins contain multiple apolipoprotein molecules, often of different types. See M. Krieger, 1995, in E.

Haber, ed., *Molecular Cardiovascular Medicine, Scientific American Medicine*, pp. 31–47.

We have seen that a general feature of coated vesicles is the ability to select specific cargo molecules; this process of cargo selection was first studied in the context of endocytosis of labeled LDL particles added to intact cells. Two general experimental approaches have been used to study how labeled LDL particles enter cells. The first method makes use of LDL that has been labeled by the covalent attachment of radioactive ^{125}I to the side chains of tyrosine residues in apoB-100 on the surfaces of the LDL particles. After cultured cells are incubated for several hours with the labeled LDL, it is possible to determine how much LDL is bound to the surfaces of cells, how much is internalized, and how much of the apoB-100 component of the LDL is transported to the lysosome and there degraded by enzymatic hydrolysis to individual amino acids. The degradation of apoB-100 can be detected by the release of ^{125}I-tyrosine into the culture medium. Figure 14-28 shows the time course of these events in receptor-mediated cellular LDL processing, determined by pulse-chase experiments with a fixed concentration of ^{125}I-labeled LDL. These experiments clearly demonstrate the order of events: surface binding of LDL → internalization → degradation. The second approach involves tagging LDL particles with an electron-dense label that can be detected by electron microscopy. Such studies can reveal the details of how LDL particles first bind to the surface of cells at sites of nascent endocytic vesicles known as *clathrin-coated*

pits, then remain associated with the coated pits as they invaginate and bud off to form clathrin-coated vesicles, and are finally transported to endosomes.

EXPERIMENTAL FIGURE 14-28 Pulse-chase experiment demonstrates precursor-product relations in cellular uptake of LDL. Cultured normal human skin fibroblasts were incubated in a medium containing ^{125}I-LDL for 2 hours at 4 °C (the pulse). After excess ^{125}I-LDL not bound to the cells was washed away, the cells were incubated at 37 °C for the indicated amounts of time in the absence of external LDL (the chase). The amounts of surface-bound, internalized, and degraded (hydrolyzed) ^{125}I-LDL were measured. Binding, but not internalization or hydrolysis, of LDL apoB-100 occurs during the 4 °C pulse. The data show the very rapid disappearance of bound ^{125}I-LDL from the surface as it is internalized after the cells have been warmed to allow membrane movements. After a lag period of 15–20 minutes, lysosomal degradation of the internalized ^{125}I-LDL commences. See M. S. Brown and J. L. Goldstein, 1976, *Cell* **9**:663.

Receptors for Macromolecular Ligands Contain Sorting Signals That Target Them for Endocytosis

The key to understanding how LDL particles bind to the cell surface and are then taken up into endocytic vesicles was the discovery of the *LDL receptor*. The LDL receptor is an 839-residue type I membrane glycoprotein; it has a long N-terminal exoplasmic segment that contains the LDL-binding domain, a single transmembrane segment, and a short C-terminal cytosolic segment. Seven cysteine-rich repeats form the LDL-binding domain, which interacts with the apoB-100 molecule in an LDL particle. Figure 14-29 shows how the LDL receptor facilitates internalization of LDL particles by receptor-mediated endocytosis. After internalized LDL particles reach lysosomes, lysosomal proteases hydrolyze their surface apolipoproteins and lysosomal cholesteryl esterases hydrolyze their core cholesteryl esters. The unesterified cholesterol is then free to leave the lysosome and be used as necessary by the cell in the synthesis of membranes or various cholesterol derivatives.

FIGURE 14-29 Endocytic pathway for internalizing low-density lipoprotein (LDL). Step 1: A cell-surface LDL receptor binds to an ApoB protein embedded in the phospholipid outer layer of an LDL particle. Interaction between the NPXY sorting signal in the cytosolic tail of the LDL receptor and the AP2 complex incorporates the receptor-ligand complex into a nascent endocytic vesicle. Step 2: Clathrin-coated pits containing receptor-LDL complexes are pinched off by the same dynamin-mediated mechanism used to form clathrin/AP1-coated vesicles on the *trans*-Golgi network (see Figure 14-19). Step 3: After the vesicle coat is shed, the uncoated endocytic vesicle (early endosome) fuses with a late endosome. The acidic pH in this compartment causes a conformational change in the LDL receptor that leads to release of the bound LDL particle. Step 4: The late endosome fuses with a lysosome, and the proteins and lipids of the free LDL particle are broken down into their constituent parts by enzymes in the lysosome. Step 5: The LDL receptor is recycled to the cell surface, where at the neutral pH of the exterior medium the receptor undergoes a

conformational change so that it can bind another LDL particle. See M. S. Brown and J. L. Goldstein, 1986, *Science* **232**:34; and G. Rudenko et al., 2002, *Science* **298**:2353.

Mutations in the human gene for the LDL receptor (*LDLR*) can cause a hereditary disease that is marked by elevated plasma LDL known as *familial hypercholesterolemia (FH)*. In patients who have one normal and one defective copy of the *LDLR* gene (heterozygotes), LDL in the blood is increased about twofold. Those with two defective *LDLR* genes (homozygotes) have LDL levels that are from fourfold to sixfold higher than normal. High levels of blood LDL can lead to excessive deposition of LDL, forming atherosclerotic plaque in coronary arteries. Without medical intervention, FH homozygotes usually die of heart attacks before reaching their late twenties.

A variety of mutations in the *LDLR* gene can cause FH. Some mutations prevent the synthesis of the LDL receptor protein; others prevent proper folding of the receptor protein in the ER, leading to its premature degradation (see Chapter 13); and still other mutations reduce the ability of the LDL receptor to bind LDL tightly. A particularly informative group of mutant receptors are expressed on the cell surface and bind LDL normally but cannot mediate the internalization of bound LDL. In individuals with this type of defect, plasma-membrane receptors for other ligands are internalized normally, but the mutant LDL receptor is not recruited into coated pits. Analysis of this mutant receptor and other mutant LDL

receptors generated experimentally and expressed in fibroblasts identified a four-residue motif in the cytosolic segment of the receptor that is crucial for its internalization: Asn-Pro-X-Tyr, where X can be any amino acid. This *NPXY sorting signal* binds to the AP2 complex, linking the clathrin/AP2 coat to the cytosolic segment of the LDL receptor in coated pits. A mutation in any of the conserved residues of the NPXY signal abolishes the ability of the LDL receptor to be incorporated into coated pits. ■

The Acidic pH of Late Endosomes Causes Most Receptor-Ligand Complexes to Dissociate

The overall rate of endocytic internalization of the plasma membrane is quite high: cultured fibroblasts regularly internalize 50 percent of their cell-surface proteins and phospholipids each hour. Most cell-surface receptors that undergo endocytosis will repeatedly deposit their ligands within the cell and then recycle to the plasma membrane to mediate internalization of ligand molecules once again. The LDL receptor, for instance, makes one round trip into and out of the cell interior every 10–20 minutes, for a total of about a hundred trips in its 20-hour life span.

Internalized receptor-ligand complexes commonly follow the pathway depicted for the M6P receptor in Figure 14-22 and the LDL

receptor in Figure 14-29. Endocytosed cell-surface receptors typically dissociate from their ligands within late endosomes, which appear as spherical vesicles with tubular branching membranes located a few micrometers from the cell surface.

The dissociation of receptor-ligand complexes in late endosomes occurs not only in the endocytic pathway but also in the delivery of soluble lysosomal enzymes via the secretory pathway (see Figure 14-23). As discussed in Chapter 11, the membranes of late endosomes and lysosomes contain V-class proton pumps that act in concert with Cl^- channels to acidify the vesicle lumen (see Figure 11-13). Most receptors, including the M6P receptor and the LDL receptor, bind their ligands tightly at neutral pH, but release their ligands if the pH is lowered to 6.0 or below. The late endosome is the first organelle encountered by receptor-ligand complexes whose luminal pH is sufficiently acidic to promote dissociation of most endocytosed receptors from their tightly bound ligands.

The mechanism by which the LDL receptor releases bound LDL particles is now understood in detail (Figure 14-30). At the endosomal pH of 5.0–5.5, histidine residues in a region known as the *β-propeller domain* of the receptor become protonated, forming a site that can bind with high affinity to the negatively charged cysteine-rich repeats in the LDL-binding domain. This intramolecular interaction sequesters the repeats in a conformation like that of a closed jackknife that cannot simultaneously bind to

apoB-100, thus causing release of the bound LDL particle. The LDL receptor in this relatively compact closed state is efficiently recycled back to the plasma membrane for another round of binding and uptake of LDL.

FIGURE 14-30 Model for pH-dependent binding of LDL particles by the LDL receptor. Schematic depiction of an LDL receptor at the neutral pH found at the cell surface and at the acidic pH found in the interior of the late endosome. (a) At the cell surface, apoB-100 on the surface of an LDL particle binds tightly to the receptor. Of the seven cysteine-rich repeats (R1–R7) in the ligand-binding arm, R4 and R5 appear to be most critical for LDL binding. (b) Within the endosome, histidine residues in the β-propeller domain of the LDL receptor become protonated. The positively charged propeller can bind with high affinity to the ligand-binding arm, which contains negatively charged residues, causing release of the LDL particle. (c) Experimental electron density and C_α backbone trace model of the extracellular region of the LDL receptor at pH 5.3 based on x-ray crystallographic analysis. In this conformation, extensive hydrophobic and ionic interactions occur between the β-propeller and the R4 and R5 repeats.

[Part (b) data from G. Rudenko et al., 2002, *Science* **298**:2353; PDB ID 1n7d.]

As described in Chapter 6, human mutations that cause a loss of function of the gene PCSK9 lead to a decrease in blood LDL. We now know that PCSK9 encodes a secreted protein whose normal function is to negatively regulate the LDL receptor. Biochemical and structural studies show that PCSK9 binds to the LDL-binding domain of the LDL receptor, thereby preventing the receptor from closing into a compact state. This more open conformation of the receptor cannot be recycled to the plasma membrane and is transported to the lysosome where it is degraded. Inhibitors of PCSK9 are a promising new class of LDL-lowering drugs.

Receptor-Mediated Endocytosis Can Down-Regulate Signaling Receptors

Signaling receptors are an important class of plasma membrane proteins that can undergo receptor-mediated endocytosis. These receptors bind to extracellular ligands and respond by generating an appropriate intracellular signal. As described in Chapter 16, the epidermal growth factor receptor (EGFR) activates a signal transduction pathway in response to the extracellular growth factor protein EGF. Treatment of cells with EGF both activates EGFR and stimulates receptor-mediated endocytosis of EGFR. Removal of EGFR from the plasma membrane by endocytosis leads to an

attenuation of the signaling response in an adaptive process, known as *down-regulation*, which extends the dynamic range of EGF concentrations over which the system can respond. The mechanism of EGFR down-regulation is one of the best understood examples of regulated endocytosis.

EGFR is a Type I cell surface glycoprotein with a large extracellular domain that binds the ligand EGF, a single transmembrane domain, and a cytoplasmic signaling domain. Normally, EGFR resides in the plasma membrane as a monomer, but when EGF is present, two copies of EGF bind to two copies of EGFR, forming a dimer that brings the cytoplasmic signaling domains of EFGR together and activates signal transduction (see Figure 16-8). Activated EGFR enters the endocytic pathway because the dimeric form of the receptor binds to clathrin/AP2-coated pits. Mutational studies of the cytoplasmic domain of EGFR have identified a di-leucine (Leu-Leu) sorting signal that is necessary for rapid endocytosis. Other proteins employ a cytoplasmic di-leucine sorting signal for entry into the endocytic pathway, but EGFR is unusual in that the cytoplasmic di-leucine signal only interacts with clathrin/AP2 complexes during ligand-induced endocytosis when the cytoplasmic domain is dimeric.

Endocytosis delivers EGFR to the late endosome, and from this location EGFR is available to recycle to the plasma membrane, in a pathway similar to that for the LDL receptor (see Figure 14-29).

Complete down-regulation depends on further transport of EGFR to the lysosome where it is degraded. In addition to enabling interaction with clathrin/AP2 complexes, ligand-induced activation of EGFR also triggers covalent modification of the cytoplasmic domain of EGFR by the small protein ubiquitin. As we will see in the next section, monoubiquitinylation marks EGFR for entry into multivesicular bodies that are ultimately degraded in lysosomes (see Figure 14-32).

KEY CONCEPTS OF SECTION 14.5

Receptor-Mediated Endocytosis

- Some extracellular ligands that bind to specific cell-surface receptors are internalized, along with their receptors, in clathrin-coated vesicles whose coats also contain AP2 complexes (see Figure 14-26).
- Sorting signals in the cytosolic domain of cell-surface receptors target them into clathrin/AP2-coated pits for internalization. Known signals include the Asn-Pro-X-Tyr, Tyr-X-X-Φ, and Leu-Leu sequences (see Table 14-2).
- The endocytic pathway delivers some ligands (e.g., LDL particles) to lysosomes, where they are degraded. Transport vesicles from the cell surface first fuse with late endosomes, which subsequently fuse with lysosomes.
- Most receptor-ligand complexes dissociate in the acidic milieu of the late endosome; the receptors are recycled to the plasma membrane, while the ligands are sorted to lysosomes (see Figure 14-29).
- Signaling receptors can be down-regulated by endocytosis. In these cases, the cytoplasmic domain of the receptors only interact with clathrin/AP2-coated pits when the receptor is in a ligand-activated state.

14.6 Directing Membrane Proteins and Cytosolic Materials to the Lysosome for Degradation

The major function of lysosomes is to degrade extracellular materials taken up by the cell and to degrade intracellular components under specific conditions. Materials to be degraded must be delivered to the lumen of the lysosome, where the various degradative enzymes reside. As we have just seen, endocytosed ligands (e.g., LDL particles) that dissociate from their receptors in the late endosome subsequently enter the lysosomal lumen when the membrane of the late endosome fuses with the membrane of the lysosome (see Figure 14-29).

It is apparent how the general vesicular trafficking mechanism discussed in this chapter can be used to deliver the luminal contents of an endosomal organelle to the lumen of the lysosome for degradation. In this section, we will discuss two further pathways. Membrane proteins delivered to the lysosome by the typical vesicular trafficking process we have discussed the previous section should ultimately be delivered to the membrane of the lysosome. How, then, are membrane proteins delivered to the interior of the lysosome for degradation? The first pathway discussed in this section, used to degrade endocytosed membrane proteins, utilizes an unusual type of vesicle that buds into the lumen of the endosome

to produce a multivesicular endosome. The second pathway that will be discussed is used by the cell for delivery of cytosolic materials to the lysosomal lumen for degradation. This second pathway, known as *autophagy*, involves the de novo formation of a double-membrane organelle known as an *autophagosome* that envelops cytosolic material, such as soluble cytosolic proteins, or sometimes organelles, such as peroxisomes or mitochondria. Both pathways lead to fusion of either the multivesicular endosome or autophagosome with the lysosome, depositing the contents of these organelles into the lysosomal lumen for degradation.

Multivesicular Endosomes Segregate Membrane Proteins Destined for the Lysosomal Membrane from Proteins Destined for Lysosomal Degradation

Resident lysosomal membrane proteins, such as V-class proton pumps and amino acid transporters, can carry out their functions and remain in the lysosomal membrane, where they are protected from degradation by the soluble hydrolytic enzymes in the lumen. Such proteins are delivered to the lysosomal membrane by transport vesicles that bud from either the *trans*-Golgi network or the endosome by the same basic mechanisms described in earlier sections. In contrast, endocytosed membrane proteins that are to be degraded are transferred in their entirety to the interior of the

lysosome by a specialized delivery mechanism. Lysosomal degradation of cell-surface receptors for extracellular signaling molecules is a common mechanism for controlling the sensitivity of cells to extracellular signals (see Chapter 15). Receptors that become damaged are also targeted for lysosomal degradation.

Early evidence that membranes can be delivered to the lumen of a membrane-bounded compartment came from electron micrographs showing membrane vesicles and fragments of membranes within endosomes and lysosomes. Parallel experiments in yeast revealed that endocytosed receptor proteins targeted to the vacuole (the yeast organelle equivalent to the lysosome) were primarily associated with membrane fragments and small vesicles within the interior of the vacuole rather than with the vacuole surface membrane.

These observations suggest that endocytosed membrane proteins can be incorporated into specialized vesicles that form at the endosomal membrane (Figure 14-31). Although these vesicles are similar in size and appearance to transport vesicles, they differ topologically. Transport vesicles bud *outward* from the surface of a donor organelle into the cytosol, whereas vesicles within the endosome bud *inward* from the surface into the lumen (away from the cytosol). Mature endosomes containing numerous vesicles in their interior are usually called **multivesicular endosomes** (or bodies). The surface membrane of a multivesicular endosome then fuses with the membrane of a lysosome, thereby delivering its

internal vesicles and the membrane proteins they contain into the lysosome interior for degradation. Thus the sorting of proteins in the endosomal membrane determines which ones will remain on the lysosome surface (e.g., pumps and transporters) and which ones will be incorporated into internal vesicles and ultimately degraded in lysosomes.

FIGURE 14-31 Delivery of plasma-membrane proteins to the lysosome interior for degradation. Early endosomes carrying endocytosed plasma-membrane proteins (blue) and vesicles carrying lysosomal membrane proteins (green) from the *trans*-Golgi network fuse with the late endosome, transferring their membrane proteins to the endosomal membrane (steps **1** and **2**). Proteins to be degraded, such as those from the early endosome, are incorporated into vesicles that bud *into* the interior of the late endosome, eventually forming a multivesicular endosome containing many such internal vesicles (step **3**). Fusion of a multivesicular endosome directly with a lysosome releases the internal vesicles into the lumen of the lysosome, where they can be degraded (step **4**). Because proton pumps and other lysosomal membrane proteins normally are not incorporated into internal endosomal vesicles, they are delivered to the lysosomal membrane and are protected from degradation. See F. Reggiori and D. J. Klionsky, 2002, *Eukaryot. Cell* **1**:11; and D. J. Katzmann et al., 2002, *Nat. Rev. Mol. Cell Biol.* **3**:893.

Many of the proteins required for inward budding of the endosomal membrane were first identified by mutations in yeast that blocked the delivery of membrane proteins to the interior of the vacuole. The current model of endosomal budding to form multivesicular endosomes is based primarily on studies in yeast, but mammalian cells appear to have essentially the same mechanism (Figure 14-32). Most cargo proteins that enter a multivesicular endosome are tagged with ubiquitin. Cargo proteins destined to enter a multivesicular endosome usually receive their ubiquitin tags at the plasma membrane, the *trans*-Golgi network, or the endosomal membrane. We have already seen how ubiquitin tagging can serve as a signal for degradation of cytosolic or misfolded ER proteins by proteasomes (see Chapters 3 and 13). When used as a signal for proteasomal degradation, the ubiquitin tag usually consists of a chain of covalently linked ubiquitin molecules (polyubiquitin), whereas ubiquitin used to tag proteins for entry into the multivesicular endosome usually takes the form of a single (monoubiquitin) molecule. In the membrane of the endosome, a ubiquitin-tagged peripheral membrane protein, known as *Hrs*, facilitates recruitment of a set of at least three different protein complexes to the membrane. These **ESCRT** (*e*ndosomal *s*orting *c*omplexes *r*equired for *t*ransport) **proteins** include the ubiquitin-binding protein *Tsg101*. The membrane-associated ESCRT proteins act to drive vesicle budding directed into the interior of the endosome as well as the loading of specific monoubiquitinylated membrane cargo proteins into the vesicle buds. Finally, the ESCRT proteins pinch off the

vesicle by forming a filamentous spiral inside the neck of a vesicle bud, releasing it and the specific membrane cargo proteins it carries into the interior of the endosome. An ATPase, known as *Vps4*, uses the energy from ATP hydrolysis to disassemble the ESCRT proteins, releasing them into the cytosol for another round of budding. In the fusion event that pinches off a completed endosomal vesicle, the ESCRT proteins and Vps4 may function like SNAREs and NSF, respectively, in the typical membrane-fusion process discussed previously (see Figure 14-11).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 14-32 Model of the mechanism for formation of multivesicular endosomes. In endosomal budding, ubiquitinylated Hrs on the endosomal membrane directs the loading of specific membrane cargo proteins (blue) into vesicle buds and then recruits cytosolic ESCRT protein complexes to the membrane (step 1). Note that both Hrs and the recruited cargo proteins are tagged with ubiquitin. After the set of bound ESCRT complexes mediates the completion and pinching off of the inwardly budding vesicles (step 2), these

complexes are disassembled by the ATPase Vps4 and returned to the cytosol (step **3**). See text for discussion. See O. Pornillos et al., 2002, *Trends Cell Biol.* **12**:569.

Retroviruses Bud from the Plasma Membrane by a Process Similar to Formation of Multivesicular Endosomes

The vesicles that bud into the interior of endosomes have a topology similar to that of enveloped virus particles that bud from the plasma membrane of virus-infected cells. Moreover, recent experiments have demonstrated that a common set of proteins is required for both types of membrane-budding events. In fact, the two processes so closely parallel each other in mechanistic detail as to suggest that enveloped viruses have evolved mechanisms to recruit the cellular proteins used in inward endosomal budding for their own purposes.

The human immunodeficiency virus (HIV) is an enveloped retrovirus that buds from the plasma membrane of infected cells in a process driven by the viral Gag protein, the major structural component of completed virus particles. Gag protein binds to the plasma membrane of an infected cell, and some 4000 Gag molecules polymerize into a spherical shell, producing a structure that looks like a vesicle bud protruding outward from the plasma membrane.

Mutational studies with HIV have revealed that the N-terminal segment of Gag protein is required for association with the plasma membrane, whereas the C-terminal segment is required for pinching off of complete HIV particles. For instance, if the portion of the viral genome encoding the C-terminus of Gag is removed, HIV buds will form in infected cells, but pinching off does not occur, and thus no free virus particles are released.

The first indication that HIV budding employs the same molecular machinery as vesicle budding into endosomes came from the observation that Tsg101, an ESCRT protein, binds to the C-terminus of Gag protein. Subsequent findings have clearly established the mechanistic parallels between the two processes. For example, Gag is ubiquitinylated as part of the process of virus budding, and in cells with mutations in Tsg101 or Vps4, HIV virus buds accumulate but cannot pinch off from the membrane (Figure 14-33). Moreover, when a segment from the cellular Hrs protein is added to a truncated Gag protein by construction of the appropriate hybrid gene, proper budding and release of virus particles is restored. Taken together, these results indicate that Gag protein mimics the function of Hrs, redirecting ESCRT proteins to the plasma membrane, where they can function in the budding of virus particles.

Parts (b), (c) Wes Sundquist, University of Utah.

FIGURE 14-33 Mechanism for budding of HIV from the plasma membrane. Proteins required for the formation of multivesicular endosomes are exploited by HIV for virus budding from the plasma membrane. (a) Budding of HIV particles from HIV-infected cells occurs by a mechanism similar to that shown in Figure 14-32, using the virally encoded Gag protein and cellular ESCRT and Vps4 proteins (steps 1–3). Ubiquitinylated Gag located near a budding particle functions like Hrs. (b) In wild-type cells infected with HIV, virus particles bud from the plasma membrane and are rapidly released into the extracellular space. (c) In cells that lack the functional ESCRT protein Tsg101, the viral Gag protein forms dense viruslike structures, but budding of these structures from

the plasma membrane cannot be completed, and chains of incomplete viral buds still attached to the plasma membrane accumulate.

Other enveloped retroviruses, such as murine leukemia virus and Rous sarcoma virus, have also been shown to require ESCRT complexes for their budding, although each virus appears to have evolved a somewhat different mechanism to recruit ESCRT complexes to the site of virus budding.

The Autophagic Pathway Delivers Cytosolic Proteins or Entire Organelles to Lysosomes

When cells are placed under stressful conditions, such as starvation, they have the capacity to recycle macromolecules for use as nutrients in a process of lysosomal degradation known as **autophagy** ("eating oneself"). The autophagic pathway begins with the formation of a flattened double-membrane cup-shaped structure that envelops a region of the cytosol or an entire organelle (e.g., a mitochondrion), forming an *autophagosome*, or *autophagic vesicle* (Figure 14-34). The outer membrane of an autophagosome can fuse with a lysosome, delivering a large vesicle, bounded by a single membrane bilayer, to the interior of the lysosome. Lipases and proteases within the lysosome degrade the autophagosome and its contents into their molecular components, just as they do when the

contents of multivesicular endosomes are delivered to the lysosome. Amino acid permeases in the lysosomal membrane then allow for the transport of free amino acids back into the cytosol for use in synthesis of new proteins.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 14-34 The autophagic pathway. The autophagic pathway allows cytosolic proteins and organelles to be delivered to the lysosome interior for degradation. In the autophagic pathway, a cup-shaped structure forms around a portion of the cytosol (*right*) or an organelle such as a mitochondrion (*left*). Continued addition of membrane eventually leads to the formation of an autophagosome that envelops its contents in two complete membranes (steps **1a** and **1b**). Fusion of the outer membrane with the membrane of a lysosome releases a single-membrane vesicle and its contents into the lysosome interior (steps **2a** and **2b**). After degradation of the protein and lipid components by hydrolases in the lysosome interior (step **3**), the released amino acids are transported across the lysosomal membrane into the cytosol (step **4**). Proteins known to participate in the autophagic pathway include Atg8, which forms a coat structure around the autophagosome.

By studying mutants with defects in the autophagic pathway, scientists have identified processes other than recycling of cellular

components during starvation that also depend on autophagy. Experiments carried out principally in *Drosophila* and mice have shown that autophagy participates in a type of quality-control mechanism that removes organelles that have ceased to function properly. In particular, the autophagic pathway can target dysfunctional mitochondria that have lost their integrity and no longer have an electrochemical gradient across their inner membrane. In certain cell types, pathogenic bacteria and viruses that are multiplying in the cytosol of host cells can be targeted to the autophagic pathway for destruction in the lysosome as part of a host defense mechanism against infection.

In each of these processes, and in all eukaryotic organisms, the autophagic pathway takes place in three basic steps. Although the mechanisms underlying each of these steps are relatively poorly understood, they are thought to be related to the basic mechanisms for vesicular trafficking discussed in this chapter.

Autophagosome Nucleation

The autophagosome is thought to originate from a fragment of a membrane-bounded organelle. The origin of this membrane has been difficult to trace because no known unique integral membrane proteins, which might serve to identify the source of this membrane, are known to be required for the formation of the autophagosome. Studies in yeast have shown that some mutants

defective in Golgi trafficking are also defective in autophagy, suggesting that the autophagosome is initially derived from a fragment of the Golgi. Autophagy that is induced by starvation appears to be a nonspecific process in which a random portion of the cytoplasm, including organelles, becomes enveloped by an autophagosome. In these cases, the site of nucleation is probably random. In cases in which organelles are enveloped by the autophagosome in response to nutrient starvation, a signal based on ubiquitin modification on the surface of the organelle targets nucleation of the autophagosome.

Autophagosome Growth and Completion

New membrane must be delivered to the autophagosome membrane in order for this cup-shaped organelle to grow. This growth probably occurs by the fusion of transport vesicles with the membrane of the autophagosome. About 30 proteins that participate in the formation of autophagosomes have been identified in genetic screens for yeast mutants that are defective in autophagy. One of these proteins is Atg8, shown in Figure 14-34, which is covalently linked to the lipid phosphatidylethanolamine and thus becomes attached to the cytoplasmic face of the autophagosome. Association of Atg8 with a membrane vesicle appears to be the key step in enabling a vesicle to fuse with the growing autophagosome.

Fusion of Atg8-containing vesicles with the autophagosome involves the formation of a cytosolic assembly of Atg12, Atg5, and Atg16.

Atg12 is similar in structure to ubiquitin, and a set of proteins related to ubiquitin-conjugating enzymes are responsible for covalently joining Atg12 to Atg5 by a process similar to that used for covalently joining ubiquitin to a target protein (see Figure 3-32). The covalently linked Atg12-Atg5 dimer then co-assembles with Atg16 to form a polymeric complex localized to the site of a growing autophagosome. By an unknown mechanism, this cytosolic complex is thought to bring about the fusion of Atg8-containing vesicles into a cup-shaped autophagosome.

Autophagosome Targeting and Fusion

The outer membrane of the completed autophagosome is thought to contain a set of proteins that target it for fusion with the membrane of a lysosome. Two vesicle-tethering proteins have been found to be required for autophagosome fusion with a lysosome, but the corresponding SNARE proteins have not been identified. Fusion of the autophagosome with the lysosome occurs after Atg8 has been released from the autophagosome membrane by proteolytic cleavage; this proteolysis step occurs only after the autophagosome has completely formed a sealed double-membrane system. Thus Atg8 protein appears to mask fusion proteins and to prevent premature fusion of the autophagosome with the lysosome.

KEY CONCEPTS OF SECTION 14.6

Directing Membrane Proteins and Cytosolic Materials to the Lysosome for Degradation

- Endocytosed membrane proteins destined for degradation in the lysosome are incorporated into vesicles that bud into the interior of the endosome. Multivesicular endosomes, which contain many of these internal vesicles, can fuse with the lysosome to deliver the vesicles to the interior of the lysosome (see Figure 14-31).
- Some of the cellular components (e.g., ESCRT) that mediate inward budding of endosomal membranes are used in the budding and pinching off of enveloped viruses, such as HIV, from the plasma membrane of virus-infected cells (see Figures 14-32 and 14-33).
- In the process of autophagy, a portion of the cytoplasm or an entire organelle (e.g., a mitochondrion) can be enveloped in a flattened membrane and eventually incorporated into a double-membrane autophagosome. Fusion of the outer vesicle membrane with the lysosome delivers the enveloped contents to the interior of the lysosome for degradation (see Figure 14-34).

Review the Concepts

1. What two modern methods allow the process of intercompartmental transport to be followed? What basic features do these experimental approaches to study protein transport have in common?

2. Vesicle budding is associated with coat proteins. What is the role of coat proteins in vesicle budding? How are coat proteins recruited to membranes? What kinds of molecules are likely to be included or excluded from newly formed vesicles? What is the best-known example of a protein likely to be involved in the pinching off of vesicles?
3. Treatment of cells with the drug *brefeldin A (BFA)* has the effect of causing Golgi membranes in the process of budding COPI vesicles to shed their vesicle coats. The result of BFA treatment is to cause the vast majority of Golgi proteins to be relocated in the ER. What inferences can be made from this observation regarding roles of coat proteins, other than promoting vesicle formation? Predict what type of mutation in ARF might have the same effect as treating cells with BFA.
4. Microinjection of an antibody known as *EAGE*, which reacts with the "hinge" region of the β subunit of COPI, causes accumulation of Golgi enzymes in transport vesicles and inhibits anterograde transport of newly synthesized vesicles from the ER to the plasma membrane. What effect does the antibody have on COPI activity? Explain the results.
5. Specificity in fusion between vesicles involves two discrete and sequential processes. Describe the first of the two processes and its regulation by GTPase switch proteins. What effect on the size of early endosomes might result from overexpression of a mutant form of Rab5 that is stuck in the GTP-bound state?

6. *Sec18* is a yeast gene that encodes NSF. Mutations of this gene produce class C mutants. What is the mechanistic role of NSF in membrane trafficking? And, as indicated by its class C phenotype, why does an NSF mutation produce accumulation of vesicles at what appears to be only one stage of the secretory pathway?
7. What feature of procollagen synthesis provided early evidence for the Golgi cisternal maturation model?
8. Sorting signals that cause retrograde transport of a protein in the secretory pathway are sometimes known as *retrieval sequences*. List the two known examples of retrieval sequences for soluble and membrane proteins of the ER. How does the presence of a retrieval sequence on a soluble ER protein result in its retrieval from the *cis*-Golgi complex? Describe how the concept of a retrieval sequence is essential to the cisternal-maturation model.
9. Clathrin adapter protein (AP) complexes bind directly to the cytosolic face of membrane proteins and also interact with clathrin. What are the four known adapter protein complexes? What observation regarding AP3 suggests that clathrin is an accessory protein to a core coat composed of adapter proteins?
10. I-cell disease is a classic example of an inherited human defect in protein targeting that affects an entire class of proteins: the soluble enzymes of the lysosome. What is the molecular defect in I-cell disease? Why does it affect the targeting of an entire class of proteins? What other types of mutations might produce the same phenotype?

11. The *trans*-Golgi network is the site of multiple sorting processes as proteins and lipids exit the Golgi complex. Compare and contrast the sorting of proteins to lysosomes with the packaging of proteins into regulated secretory vesicles such as those containing insulin. Compare and contrast the sorting of proteins to the basolateral versus apical cell surfaces in MDCK cells and in hepatocytes.
12. What does the budding of influenza virus and vesicular stomatitis virus (VSV) from polarized MDCK cells reveal about the sorting of newly synthesized plasma membrane proteins to the apical or basolateral domains? Now consider the following result: a peptide with a sequence identical to that of the VSV G protein cytoplasmic domain inhibits targeting of the G protein to the basolateral surface and has no effect on HA targeting to the apical membrane, but a peptide in which the single tyrosine residue is mutated to an alanine has no effect on G protein basolateral targeting. What does this tell you about the sorting process?
13. Describe the role of pH in regulating the interaction between mannose 6-phosphate and the M6P receptor. Why does a rise in endosomal pH lead to the secretion of newly synthesized lysosomal enzymes into the extracellular medium?
14. What mechanistic features are shared by (a) the formation of multivesicular endosomes by budding into the interior of an endosome and (b) the outward budding of HIV virus at the cell surface? You wish to design a peptide

inhibitor/competitor of HIV budding and decide to mimic a portion of the HIV Gag protein in a synthetic peptide. Which portion of the HIV Gag protein would be a logical choice? What normal cellular process might this inhibitor block?

15. The endocytic and autophagic pathways serve two fundamentally different roles, but both deliver their vesicles to the lysosome. What are the fundamental differences between the two pathways? Describe the three basic steps in the formation and fusion of autophagosomes.
16. Describe the location and pH sensitivity of the receptor-ligand interaction in the LDL receptor-mediated endocytosis pathway.
17. What do mutations in the cytoplasmic domain of the LDL receptor that cause familial hypercholesterolemia reveal about the receptor-mediated endocytosis pathway?

CHAPTER 15

Receptors, Hormones, and Cell Signaling

OUTLINE

15.1 Signal Transduction Pathways: From Extracellular Signal to Cellular Response
15.2 Studying Cell-Surface Receptors and Signal Transduction Proteins
15.3 Structure and Mechanism of G Protein–Coupled Receptors
15.4 Regulating Metabolism of Many Cells: G Protein–Coupled Receptors That Activate or Inhibit Adenylyl Cyclase
15.5 Regulating Protein Secretion and Muscle Contraction: Ca^{2+} Ions as Second Messengers in Multiple Signal Transduction Pathways
15.6 Vision: How the Eye Senses Light

No cell lives in isolation; life requires that all cells sense stimuli in their environment and respond appropriately with adaptations that affect their growth, health, function, or development. Many cells sense physical stimuli such as mechanical pressure (touch) and heat (see Chapter 21). Phototactic single-celled algae sense light (see Chapter 1), and in this chapter we see how cells in the human retina sense light and respond by sending signals to the brain. Metazoan cells sense a wide variety of environmental chemicals, including nutrients such as sugars and amino acids as well as oxygen, toxic compounds, and diverse molecules that convey taste (tastants) and odor (odorants). Many cells sense a reduction in oxygen levels in the blood and respond by activating the HIF1α transcription factor which, in turn, activates expression of genes that enable the cells and the organism to adapt to low oxygen (see Chapter 21).

Many types of cells release particular chemicals that can influence the behavior of another cell; these are often called *extracellular* (outside of the cell) **signaling molecules**, or simply *signals*. The release and reception of such signals is a fundamental process, known as **cellular communication**, that shapes the development and function of every living organism. Cells that communicate through extracellular signals include single-cell prokaryotic and eukaryotic microorganisms — such as bacteria, yeasts, algae, slime molds, and protozoans. In Chapter 1 we saw how secreted molecules called *pheromones* coordinate the aggregation of free-living yeast cells for sexual mating.

This chapter and the next focuses on hormones and other extracellular signaling molecules that function *within* multicellular animals. These signaling molecules function to control a variety of processes, including the metabolism of sugars, fats, and amino acids; the induction or repression of specific genes that in turn affect the growth, differentiation, and function of cells and tissues; the synthesis and secretion of many proteins; and the composition of intracellular and extracellular fluids. For example, when the concentration of certain hormones rises, that informs cells that the organism is threatened (adrenaline and the fight-or-flight response) or that excess nutrients are present and should be stored for future use (insulin triggering the uptake of glucose into muscle for storage as glycogen).

The primary biological function of many of the molecules used as signals — hormones, pheromones, and some neurotransmitters — is the transfer of information. Some molecules used as signals have multiple functions. For example, some nutrients both act as signals and serve as fundamental building blocks of biomolecules (amino acids, sugars) or as sources of energy (oxygen, glucose, fatty acids).

The cell that receives a signal — termed the **target cell** — must be able to detect the signaling molecule. Typically, the signaling molecule binds noncovalently to a specific protein in the cell, typically called the **receptor**, that contains a binding site for the signaling molecule. The signaling molecule that binds a receptor is often called the **ligand** of the receptor. Receptors bind a single type of molecule or a group of closely related molecules.

After detecting a signaling molecule, the cell needs to generate a response. Upon binding their ligand, receptors undergo a conformational change that enables them to bind to other proteins in the cytosol or attached to a membrane, often the plasma membrane (Figure 15-1, steps **1** and **2**). In binding to these proteins, the receptor may activate (or inhibit) them, sometimes by enzymic modification, such as phosphorylation. Often there are multiple biochemical or biophysical steps that form a pathway from the initial detection of the signal by the receptor to the final (downstream) responses of the cell. The series of steps leading from initial detection to the final response is termed a **signal transduction pathway**. Signal transduction pathways ultimately

lead to activation (or in some cases inhibition) of one or more **effector proteins** — often enzymes or transcription factors or cytoskeletal proteins — that lead directly to changes in cellular activities (Figure 15-1, steps 3 – 5). Some signal transduction pathways contain just one or two intermediates; others can involve over a dozen.

FIGURE 15-1 Signal transduction pathways. In this generalized pathway, a receptor protein R binds a ligand H (step 1), triggering a conformational change in the receptor (R^*) that enables it to bind to and activate a signal transduction protein S_1 (step 2). In many signaling pathways this is a GTP-binding protein or a protein kinase or phosphatase. S_1 in turn binds to and activates (or inhibits) other signal transduction proteins (step 3), S_2, that in turn activate other signaling proteins, here S_3, S_4, and S_5 (step 4). Some signaling proteins (here S_2) can activate multiple types of different downstream proteins. Certain signal transduction proteins bind and activate an effector protein, E (step 5), which can be an enzyme, transcription factor, transport protein, ion channel, or other type of protein. Signal amplification is a characteristic of many signal transduction pathways, in which activation of a single receptor molecule can lead to activation of multiple signal transduction and effector proteins (step 3). Virtually all signal transduction pathways have feedback controls whereby a protein in the signal transduction pathway (here S_5) or an effector protein modifies either the receptor (step 6a) or an early protein in the pathway

(step 6b), thus inhibiting or blocking an early step in that pathway. In many pathways these feedback controls trigger receptor degradation, lowering the numbers of receptors and thus the sensitivity of the cell to the ligand.

In any cell in multicellular organisms, multiple receptors are simultaneously activated by different extracellular signals, and each of these receptors in turn can activate a different signal transduction pathway. Complex information-processing networks help coordinate the cell's responses to these multiple signals and lead to an appropriate change in the cell's pattern of gene expression and metabolism.

In this chapter, we first discuss some basic properties of receptors and the signal transduction pathways they activate, then introduce key techniques for studying receptors and proteins in signaling pathways. We next focus on the largest and evolutionarily most ancient class of receptors — the **G protein–coupled receptors**. We will see several of the many important signal transduction pathways they activate and the functions these pathways play in biology.

15.1 Signal Transduction Pathways: From Extracellular Signal to Cellular Response

Signaling Molecules Can Act Locally or at a Distance

As noted above, cells respond to many different types of signals — some originating from outside the organism, some internally generated. Within a multicellular organism, signaling molecules that are generated internally can be described by how they reach their target. Some signaling molecules are transported long distances from their site of synthesis — for example, by movement through the blood; others have more local effects. In animals, signaling by extracellular molecules can be classified into three types based on the distance over which the signal acts (Figure 15-2a–c).

FIGURE 15-2 Types of extracellular signaling. (a–c) Cell-to-cell signaling by extracellular chemicals occurs over distances from a few micrometers in paracrine and autocrine signaling to several meters in endocrine signaling. (d) Proteins attached to the plasma membrane of one cell can interact directly with cell-surface receptors on adjacent cells.

In *endocrine* signaling, the signaling molecules act on target cells distant from their site of synthesis. The signaling molecules are synthesized and secreted by signaling cells (e.g., those found in endocrine glands) and transported through the circulatory system to the target cells. The term **hormone** generally refers to signaling molecules that mediate endocrine signaling. Insulin secreted by the pancreas and epinephrine secreted by the adrenal glands are examples of endocrine signals that travel through the blood, and thus they are termed *hormones*. Defects in endocrine signaling can result in human diseases — for example, defects in insulin signaling can cause diabetes.

In **paracrine** signaling, the signaling molecules released by a cell affect only those target cells in close proximity. An example is a neuron releasing a neurotransmitter that acts on an adjacent neuron. In addition to neurotransmitters, many of the protein **growth factors** that regulate development in multicellular organisms act at short range. Several of the developmentally important signaling proteins that we discuss in Chapter 16 diffuse away from the signaling cell, forming a concentration gradient, and induce different responses in nearby cells depending on their distances from the signaling cells and thus on the local concentration of the signaling protein. In some cases, paracrine signaling molecules, exemplified by TGF-β, are secreted by a cell and then trapped nearby in the web of extracellular macromolecules

termed the *extracellular matrix* until freed to bind to cell-surface receptors on a nearby cell (see Chapters 16 and 20).

In *autocrine* signaling, cells respond to substances that they themselves release. This type of signaling is particularly characteristic of tumor cells. Many tumor cells release growth factors that stimulate inappropriate, unregulated self-proliferation.

Some signaling molecules are integral membrane proteins located on the cell surface (Figure 15-2d). The targets of these relatively immobile membrane signals are receptors on the surface of adjacent cells, whose proliferation or differentiation are controlled by the signal. In other cases, proteolytic cleavage of a membrane-bound signaling protein releases the extracellular domain, which functions as a soluble signaling molecule that can act locally or at a distance (see Chapter 16).

Some signaling molecules can act at both short and long ranges. For example, epinephrine (also known as *adrenaline*) functions as a neurotransmitter (paracrine signaling) and as a hormone (endocrine signaling). As a hormone, it helps initiate the fight-or-flight response to a sudden danger in the environment discussed in Section 15.4.

Signal Transduction Pathways Can Produce Rapid, Short-Term or Slow, Long-Term Changes in Cells, or Both

The effector proteins in signal transduction pathways are often enzymes or transcription factors that induce two major types of cellular responses: rapid short-term changes in protein activities (seconds-to-minutes) or slower long-term changes (hours-to-days). Rapid changes are typically consequences of modifications to specific preexisting enzymes and other proteins that alter their activity or function. Changes to these proteins are often initiated by covalent modifications such as phosphorylation or ubiquitinylation or by binding of ions or molecules such as Ca^{2+} or cAMP. Such modifications can induce changes in cellular metabolism of sugars, amino acids, and lipids; can induce secretion of hormones; and can induce in nerve cells the electric signals called *action potentials* (Chapter 23). Slower, long-term changes are typically consequences of changes in gene expression, either activating or inhibiting synthesis of specific proteins. In this case, the effector proteins are usually transcription factors. Long-term changes in the amounts and activities of specific proteins within cells are critical for cell proliferation, cell differentiation, and organismal development.

Receptors Are Allosteric Proteins That Activate Signal Transduction Pathways

The interacting surfaces of a receptor and ligand are complementary (see Figure 2-12), held together by multiple weak, noncovalent forces, including ionic, van der Waals, and hydrophobic interactions. In most cases, the binding of the ligand to the receptor causes the receptor to change from an inactive conformation (R) to an active conformation (R*).

$$\mathrm{R} + \mathrm{L} \rightarrow \mathrm{RL} \rightarrow \mathrm{R^*L}$$

Only the active R* conformation of the receptor can trigger the subsequent steps in the signal transduction pathway (see Figure 15-1) because only it can bind to, and subsequently activate or inhibit, a protein that initiates the signaling pathway. The site on the receptor that interacts with the next molecule in the signal transduction pathway typically is not the site where the ligand binds. Thus receptors are considered to be *allosteric* proteins (see Chapter 3). As with all allosteric proteins, there is an equilibrium between the R and R* forms of the receptor.

$$\begin{aligned}
&\mathrm{R} = \text{inactive} \quad \mathrm{R^*} = \text{active} \\
&\text{No ligand } \mathrm{R} \rightleftarrows \mathrm{R^*} \\
&\text{With ligand } \mathrm{R} \rightleftarrows \mathrm{R^*}\ (shifts\ right)
\end{aligned}$$

In the absence of the ligand, the equilibrium is far to the left; most of the receptor is in the inactive R conformation. In the presence of ligand, the equilibrium is changed, such that more receptors are in the active R* conformation. In other words, the ligand binds much more tightly to the R* than the R conformation, thus pushing the equilibrium to the right and activating the signal transduction pathway.

Receptors Can Be in the Cytosol, Nucleus, or on the Cell Surface Membrane

How a signaling molecule gains access to its receptor's binding site depends on where the receptor is located, whether inside the cell or partially exposed to the extracellular fluid at the cell surface.

Extracellular signal molecules that bind to receptors inside the cell must be able to cross the plasma membrane. Some are hydrophobic and can spontaneously diffuse across the plasma membrane's bilayer without the need for transport proteins (see Chapter 11). Others, such as amino acids, are hydrophilic and, as discussed in Chapter 11, can enter the cell only with the aid of transporter proteins in the plasma membrane. Once inside the cell, these signaling molecules bind to receptors that usually are water-soluble

proteins located in the cytosol, the nucleus, or some other intracellular organelle (Figure 15-3).

FIGURE 15-3 Overview of cell signaling. Hydrophobic signaling molecules, such as steroids and related molecules, diffuse through the plasma membrane (step 1) and bind to receptors in the cytosol (step 2). The receptor-signal complex moves into the nucleus (step 3), where it can bind to transcription-control regions in DNA and activate or repress gene expression. The majority of

signaling molecules, including small molecules (adrenaline, acetylcholine), peptides (yeast mating factors, glucagon), and proteins (insulin, growth hormone), are hydrophilic and cannot diffuse across the cell membrane. These molecules bind to specific cell-surface receptor proteins, triggering a conformational change in the receptor, thus activating it (step **4**). The activated receptor then activates one or more downstream signal transduction proteins or small-molecule second messengers (step **5**), which eventually leads to activation of one or more effector proteins (step **6**). The end result of a signaling cascade can be modification of specific cytosolic effector proteins, predominantly enzymes, leading to short-term changes in cellular function, metabolism, or movement (step **7a**). Alternatively, an effector protein can move into the nucleus, triggering a long-term change in gene expression (step **7b**). Termination or down-modulation of the cellular response is often caused by negative feedback from intracellular signaling molecules (step **8**) and by removal of the extracellular signal (step **9**).

One large class of hydrophobic signaling molecules spontaneously diffuses through the plasma membrane and binds to members of the nuclear receptor family of transcription factors. These signaling molecules are primarily steroids, retinoids, vitamin D, and thyroid hormone (thyroxine). In most cases, as we saw in Chapter 8, the receptor is located in the cytosol, and the receptor-hormone complex moves into the nucleus, binds to specific regulatory sequences in DNA, and activates or represses expression of specific target genes (see Figure 15-3). In other cases, the receptor is already positioned in the nucleus, bound to its corresponding enhancers or promoters on the DNA. The conformational change in the receptor induced by ligand binding permits transcriptional co-activators to bind and induce gene transcription.

In this chapter and the next, we focus on extracellular signaling molecules — small molecules, peptides, and proteins — that initiate signal transduction pathways without crossing the plasma membrane. Indeed, they are frequently too large and too hydrophilic to diffuse through the plasma membrane. These bind to **cell-surface receptors** that are integral membrane proteins embedded in the plasma membrane (see Figure 15-3). Cell-surface receptors generally consist of three discrete topological domains, or segments: an extracellular domain facing the extracellular fluid, a plasma-membrane-spanning (transmembrane) domain, and an intracellular domain facing the cytosol.

The signaling molecule binds to a structurally complementary site of the receptor that is accessible from the extracellular fluid. The binding site may be located on the extracellular domain or within the membrane-spanning domain of the receptor. Binding of the ligand induces a conformational change in the receptor that is transmitted through the membrane-spanning domain to the cytosolic domain. This allosteric change results in the receptor's binding to, and subsequently activating or inhibiting, other proteins in the cytosol or attached to the plasma membrane. Thus the information that an extracellular signal is present is *transduced* across the plasma membrane and delivered to the cell interior.

In eukaryotes, there are about a dozen classes of cell-surface receptors, which activate several types of intracellular signal

transduction pathways. Our knowledge of signal transduction has advanced greatly in recent years, in part because these receptors and pathways are highly conserved and function in essentially the same way in organisms as diverse as worms, flies, mice, and humans. Studies using one organism often provide insights into signal transduction pathways in other organisms. For example, information gleaned from genetic studies in flies or worms can be combined with the information from biochemical analyses of mammalian cells to enable researchers to trace many entire signaling pathways from binding of ligand to final cellular response.

Most Receptors Bind Only a Single Type of Ligand or a Group of Closely Related Ligands

Like an enzyme binding to a substrate, each type of receptor binds only a single type of molecule or a group of very closely related ones. For example, the growth factor receptor binds growth factor, but not insulin or other protein hormones (Figure 15-4). Testosterone receptors bind the steroid testosterone but not other steroid hormones such as estrogen. The *binding specificity* of a receptor refers to its ability to bind or not bind closely related substances.

FIGURE 15-4 A single growth hormone protein binds simultaneously to two growth hormone receptors through multiple weak, noncovalent forces. (a) As determined from the three-dimensional structure of the 1 growth hormone: 2 growth hormone receptor complex, 28 amino acids in the hormone are at the binding interface with the first receptor protein. To determine which amino acids are important in ligand-receptor binding, researchers mutated each of these amino acids one at a time to alanine and measured the effect on receptor binding. From this study, it was found that only eight amino acids on growth hormone (green) contribute 85 percent of the energy that is responsible for tight receptor binding; these amino acids are distant from each other in the primary sequence but adjacent in the folded protein. Similar studies showed that two tryptophan residues (blue) in the receptor contribute most of the energy responsible for tight binding of growth hormone, although other amino acids at the interface with the hormone (yellow) are also important. (b) Binding of growth hormone to one receptor molecule is followed by (c) binding of a second receptor (purple) to the opposing side of the hormone; this involves the same set of yellow and blue amino acids on the receptor but different residues (light blue) on the hormone.

[Data from B. Cunningham and J. Wells, 1993, *J. Mol. Biol*. **234**:554; and T. Clackson and J. Wells, 1995, *Science* **267**:383.]

Organisms have evolved to be able to use a single ligand to stimulate different cell types to respond in distinct ways. Different cell types often have different receptors that bind the same ligand, and

activation of each receptor type induces a different intracellular signal transduction pathway. For instance, the surfaces of skeletal muscle cells, heart muscle cells, and the pancreatic acinar cells that produce hydrolytic digestive enzymes each have different types of receptors for acetylcholine. In a skeletal muscle cell, release of acetylcholine from a motor neuron innervating the cell (paracrine signaling) triggers muscle contraction by activating an ion channel. In heart muscle, the release of acetylcholine by certain neurons activates a G protein–coupled receptor that through a signal transduction pathway opens a K^+ channel, reducing the rate of contraction and lowering the heart rate. Acetylcholine binding to a receptor on pancreatic acinar cells induces a rise in the cytosolic concentration of Ca^{2+} that triggers secretion of digestive enzymes to facilitate digestion of a meal. Thus the activation by acetylcholine of different types of acetylcholine receptors produces different cellular responses, depending on the receptor and cell type.

Sometimes, the same receptor found on different cell types can, in response to binding the ligand, activate different signal transduction pathways leading to activation of different effectors. For example, the same receptor for the hormone epinephrine (the β-adrenergic receptor) is found on liver, muscle, and fat (adipose) cells. As we see in Section 15.4, epinephrine binding to its receptor stimulates depolymerization of glycogen to glucose in the first two cell types but hydrolysis and secretion of stored fat in adipose cells. In these ways, the same ligand can induce different cells to respond in a

variety of ways, often in a manner that coordinates the overall response of the organism. This property is known as the *effector specificity* of the receptor-ligand complex.

Most Receptors Bind Their Ligands with High Affinity

Binding of a single ligand to a receptor usually can be viewed as a simple reversible reaction, where the receptor is represented as R, the ligand as L, and the activated receptor-ligand complex as R*L:

$$\mathrm{R} + \mathrm{L} \quad \underset{k_{\mathrm{on}}}{\overset{k_{\mathrm{off}}}{\leftrightarrows}} \quad \mathrm{R}^{*}\mathrm{L} \tag{15-1}$$

where k_{on} is the kinetic rate constant for formation of a receptor-ligand complex from free ligand and receptor and k_{off} is the rate constant for dissociation of a ligand from its receptor. We define [R] and [L] as the concentrations of free receptor (i.e., receptor without bound ligand) and ligand, respectively, and [R*L] as the concentration of the receptor-ligand complex. At equilibrium, the rate of formation of the receptor-ligand complex, $[\mathrm{R}][\mathrm{L}]\ k_{\mathrm{on}}$, is equal to the rate of its dissociation, $[\mathrm{R}^{*}\mathrm{L}]\ k_{\mathrm{off}}$: thus at equilibrium,

$$[\mathrm{R}]\ [\mathrm{L}]\ k_{\mathrm{on}} = [\mathrm{R}^{*}\mathrm{L}]\ k_{\mathrm{off}}$$

The affinity of a signal molecule's binding to its receptor is typically quantified by the **dissociation constant** for binding (K_d). The dissociation constant K_d is the ratio of the two rate constants, $K_\mathrm{d} = k_\mathrm{off}/k_\mathrm{on}$. Equivalently, at equilibrium we can write this equation as:

$$K_\mathrm{d} = \frac{[\mathrm{R}][\mathrm{L}]}{[\mathrm{R}^*\mathrm{L}]} \tag{15-2}$$

The lower the value of the dissociation constant K_d, the tighter the binding (see Chapter 2 and below) and the more *stable* the receptor-ligand complex.

A way of seeing this key point is that when the concentration of ligand equals K_d (when $[\mathrm{L}] = K_\mathrm{d}$), then the concentration of free receptor [R] must equal the concentration of the receptor-ligand complex $[\mathrm{R}^*\mathrm{L}]$. Since the total amount of receptor equals the sum of the free and ligand-bound receptors:

$$[\mathrm{R_T}] = [\mathrm{R}^*\mathrm{L}] + [\mathrm{R}] \tag{15-3}$$

when the system is at equilibrium, half of the receptors have a ligand bound. The smaller the K_d, the lower the ligand concentration required to bind 50 percent of the cell-surface

receptors. A common method for experimentally determining the K_d of ligand/receptor binding is described in Section 15.2. The K_d for a binding reaction is similar to the Michaelis constant, K_m, which reflects the affinity of an enzyme for its substrate (see Chapter 3).

Signaling systems have evolved such that when an extracellular signal is not present or is present at only very low concentrations, very little receptor is bound to the ligand ([R*L] is low), and the cells are in what is called the *basal* or *unstimulated state*. A rise in the concentration of an extracellular signaling molecule, as when hormones are released into the blood, usually induces a proportional response in the target cell as more and more cellular receptors bind to their ligand and switch to their active conformations.

We can see this principle in practice by comparing the fraction of receptors bound by the hormone insulin at different levels of insulin present in the blood. The K_d for binding of insulin to its receptor on liver cells is 1.4×10^{-10} M (0.14 nM). The normal concentration of insulin in the blood is about 5×10^{-12} M. By substituting this value of L and the K_d into Equation 15-2, we can calculate the fraction of total insulin receptors with bound insulin, $[R^*L]/[R_T]$ at equilibrium as 0.0344; that is, about 3 percent of the total insulin receptors will have insulin bound to them in this unstimulated state. Ingesting glucose during a meal induces insulin secretion from the

pancreas (see Chapter 21). If the insulin concentration rises fivefold to 2.5×10^{-11} M, the number of receptor-hormone complexes will rise proportionately, almost fivefold, and about 15 percent of the total receptors will have insulin bound to them. If the extent of the induced cellular response is proportional to the number of active insulin-receptor complexes [RL], as is often the case, then the cellular response (changes in the activities of proteins and genes in the signal transduction pathway) will also increase by about fivefold.

We now turn our attention to events in the signal transduction pathway after the receptor is activated, focusing on the small molecules and proteins that most commonly participate in signal transduction pathways.

Second Messengers Are Used in Most Signal Transduction Pathways

Many signal transduction pathways include a step in which specific small molecules such as cyclic AMP and cyclic GMP are synthesized or in which the cytosolic concentration of an ion such as Ca^{2+} is increased. Such small molecules and ions in signaling pathways are often called **second messengers,** the first messenger being the extracellular signaling molecule itself (Figure 15-5). These second messenger molecules and ions then bind to and activate (or sometimes inhibit) specific intracellular proteins. Both the change

in concentration of a second messenger and its action on another protein are key steps in the pathway that ultimately results in a change in the physiological state of the cell in response to the initial signal/stimulus (first messenger). As an example, increases in the concentration of Ca^{2+} in the cytosol can in different cells trigger protein secretion, cell movement, or muscle contraction.

FIGURE 15-5 Four common compounds that function as intracellular second messengers. The major direct effect or effects of each compound are indicated below its structural formula. Calcium ions (Ca^{2+}) and several membrane-bound phosphatidylinositol derivatives also act as second messengers.

Protein Kinases and Phosphatases Participate in Signal Transduction Pathways by Covalently Modifying and Thus Activating or Inhibiting a Wide

Variety of Proteins That Control Cellular States

Commonly in a signal transduction pathway, proteins are activated or deactivated at multiple steps. One of the most common and reversible mechanisms for changing the activity of a protein is phosphorylation. **Protein kinases (PKs)** add phosphate groups to specific residues of target proteins, while **protein phosphatases** remove phosphate groups from these residues (see Figure 3-36). Depending on the target protein, phosphorylation can change its enzymatic activity or its ability to bind to other proteins and thus plays a critically important role in determining the functional state of a cell. A typical mammalian cell expresses a hundred or more different types of kinases, each of which can phosphorylate — and thus affect the activity of — multiple target proteins.

The catalytic domains of all known protein kinases have a similar three-dimensional structure (see Figure 3-37) and highly conserved amino acids cluster around the catalytic site. Some form the *nucleotide-binding pocket* that binds ATP, positioning it such that its gamma phosphate can be transferred to the OH moiety of its substrate (see Figure 3-38). As detailed in Chapter 3, all kinases recognize their specific protein substrates by binding not only to the side chain of the serine, threonine, or tyrosine to be phosphorylated but also to specific amino acid residues that surround the target residue. Thus one can analyze the amino acid sequences

surrounding tyrosine, serine, and threonine residues in a protein and make a good prediction as to which kinases might phosphorylate those residues.

The catalytic activity of all kinases is highly regulated; commonly it is modulated by the binding of other proteins to the kinase and by changes in the concentrations of various small intracellular signaling molecules and metabolites. Many kinases are themselves activated by phosphorylation, resulting in cascades of kinases, one phosphorylating the next in the cascade. An example is protein kinase A (PKA), a kinase that phosphorylates proteins that regulate many aspects of cell metabolism (see Section 15-4). In its inactive, unphosphorylated form, critical residues in the activation loop are in the wrong position to bind ATP and its protein substrates (see Figures 3-38 and 15-6a). When a critical threonine residue in the activation loop is phosphorylated by PKA or by another kinase, the conformation of the loop changes, creating the binding site for ATP and its substrates, thus activating catalytic activity (Figure 15-6b). In this chapter and the next we see that many other kinases are activated in a similar manner.

EXPERIMENTAL FIGURE 15-6 Molecular structures of protein kinase A (PKA) in its catalytically inactive, unphosphorylated form (a) and after activation by phosphorylation of a threonine residue in the activation loop (b). Phosphorylation of PKA at threonine-197 (pT197) leads to a marked conformational change in the activation loop, a change that promotes binding of both ATP and its substrate proteins. A similar phosphorylation-dependent mechanism activates many other kinases (see Figure 3-38). Phosphorylation of threonine-197 is also required for binding of PKA to its inhibitory subunit R (see Figure 15-21a) and thus for its regulation by cAMP (see Section 15.4). PKA can autophosphorylate itself on T197 and other cellular kinases can also autophosphorylate this residue.

[Data from J.M. Steichen et.al., *J. Biol. Chem*. **287**:14672.]

Many proteins are substrates for multiple kinases, each of which usually phosphorylates different amino acids in the protein. Each phosphorylation event has the potential to modify the activity of a particular target protein in a different way, some activating its function, others inhibiting it. An example we will encounter later is glycogen phosphorylase kinase, a key regulatory enzyme in glucose metabolism (see Figure 15-22). When activated by a signal transduction pathway, this enzyme phosphorylates and thereby activates the enzyme that breaks down glycogen into glucose. In many cases, addition of a phosphate group to an amino acid creates a binding surface that allows a second protein to bind; in the following chapter and Chapter 19 we will encounter many examples of kinase-driven assembly of multiprotein complexes.

Importantly, the activity of all protein kinases is opposed by the activity of protein phosphatases, some of which themselves are regulated by extracellular signals. Thus the activity of a protein in a cell can be a complex function of the activities of multiple kinases and phosphatases that act on it. Several examples of this phenomenon that occur in regulation of the cell cycle are described in Chapter 19.

GTP-Binding Proteins Are Frequently Used in Signal Transduction Pathways as On/Off Switches

Many signal transduction pathways contain members of the **GTPase superfamily of proteins**, which are found in all prokaryotic and eukaryotic cells. All of these proteins bind GTP and all can be turned off and on like a molecular switch. They exist in two forms (see Figure 3-35): (1) an active ("on") form with bound GTP (guanosine triphosphate) and (2) an inactive ("off") form with bound GDP (guanosine diphosphate). The GTP-bound "on" form binds to and modulates the activity of specific target proteins, whereas the "off" form cannot affect the activity of target proteins.

Two large classes of GTPase switch proteins are used in signal transduction pathways. **Heterotrimeric G proteins** directly bind to and are activated by certain cell-surface receptors. As we see in Section 15.3, G protein–coupled receptors function as guanine nucleotide exchange factors (GEFs): that is, they activate the heterotrimeric G protein to which they are coupled by triggering its release of GDP. The G protein then spontaneously binds GTP, favored by the high intracellular concentration of GTP relative to that of GDP. Binding of GTP induces a conformational change in the G protein to the active, "on" form (see Figure 3-35). The principal conformational changes involve two highly conserved segments of the GTP-binding protein, termed *switch I* and *switch II*, that allow the protein to bind to and activate downstream signaling proteins (Figure 15-7).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 15-7 Switching mechanism of monomeric G proteins. The ability of a G protein to interact with other proteins and thus transduce a signal differs between the GTP-bound "on" state and GDP-bound "off" state. (a) In the active "on" state, two domains, termed *switch I* (green) and *switch II* (blue), are bound to the terminal γ phosphate of GTP through interactions with the backbone amide groups of conserved threonine and glycine residues. When bound to GTP in this way, the two switch domains are in a conformation such that they can bind to and thus activate specific downstream effector proteins. (b) Removal of the γ phosphate by GTPase-catalyzed hydrolysis causes switch I and switch II to relax into a different conformation, the inactive "off" state; in this state, they are unable to bind to effector proteins. The ribbon models shown here represent both conformations of Ras, a monomeric G protein. A similar spring-loaded mechanism switches the alpha subunit in

heterotrimeric G proteins between the active and inactive conformations by movement of three, rather than two, switch segments.

[Data from I. Vetter and A. Wittinghofer, 2001, *Science* **294**:1299.]

After a brief time, the active G protein is shut off, converting back to the inactive form. A GTPase, which is often part of the GTP-binding protein itself, slowly hydrolyzes the bound GTP to GDP and P_i, thereby altering the conformation of the switch I and switch II segments so that they are unable to bind to the target protein.

The rate of GTP hydrolysis determines the length of time the GTP-binding protein remains in the active conformation and is able to signal its downstream target proteins: the slower the rate of GTP hydrolysis, the longer the protein remains in the active, GTP-bound state. The rate of GTP hydrolysis is often modulated by other proteins. For instance, both *GTPase-activating proteins (GAPs*) and *regulators of G protein signaling (RGSs)* accelerate GTP hydrolysis (see Figure 3-35). Many regulators of G protein activity are themselves controlled by extracellular signals.

Monomeric (often called *low-molecular-weight*) **G proteins**, including Ras and various Ras-like proteins such as Ran and Sar, do not directly bind to receptors but act as intermediate proteins in signal transduction pathways (Chapter 16). Monomeric G proteins play crucial roles in many pathways that regulate cell division and cell

motility. For this reason, mutations in genes encoding these G proteins frequently lead to cancer.

Signal Amplification and Feedback Repression Characterize Most Signal Transduction Pathways

Two essential features of most signal transduction pathways are *signal amplification* and *feedback repression*. In amplification (see Figure 15-1, step **3**), a single signaling molecule binding to one receptor protein can substantially alter the activity of a biochemical pathway within a cell. For instance, we see later in the chapter that a single photon absorbed by a photoreceptor in a rod cell in the eye (the physical stimulus) produces a measurable change in the membrane electrical potential. The process that enhances the effect of a signaling molecule is called *amplification*.

In amplification, the activation of a single receptor molecule can lead to activation of more than one molecule of a downstream intermediate protein in the signal transduction pathway. Each intermediate protein can also activate multiple proteins downstream of it, resulting in a cascade of activation. The extent of amplification depends on the number of steps in the signal transduction cascade and on the relative concentrations of the various components. As discussed later in the chapter, we are able to

detect a flash of as few as five photons because the signal transduction pathway amplifies the signal from a few photons enough to change the activities of Na^+ and Ca^{2+} ion channels responsible for the change in membrane potential. The ability to respond to a single photon makes night vision possible.

Cells must be able to suppress or even turn off a signal transduction pathway once the cell has adequately responded to the signal or the signal has been removed. Virtually all signal transduction pathways have feedback controls that will shut down the pathway: once activated, an effector protein modifies either the receptor or one of the proteins that operates in the early stages of the signal transduction pathway, thus blocking the downstream cellular responses (see Figure 15-1, steps **6a** and **6b**). In many pathways, these feedback controls trigger loss of receptor activity or even receptor degradation, lowering the number of functional receptors. The cell thus becomes much less sensitive to the ligand. Such feedback responses are sometimes referred to as *adaptation*.

We next describe how cell-surface receptors and signal transduction proteins are identified and characterized biochemically, focusing on components of signal transduction pathways that have been conserved through evolution. We then turn to an in-depth discussion of a very large and evolutionarily conserved class of receptors found in organisms from fungi to humans: the G protein–coupled receptors. Other large classes of cell-surface receptors and

the intracellular signaling pathways they activate are explored in Chapter 16.

KEY CONCEPTS OF SECTION 15.1

Signal Transduction Pathways: From Extracellular Signal to Cellular Response

- All cells communicate through extracellular signals. In unicellular organisms, extracellular signaling molecules regulate interactions between individuals, while in multicellular organisms, they mainly regulate physiology and development.
- Extracellular signals include membrane-anchored and secreted proteins or peptides (e.g., vasopressin and insulin), small hydrophobic molecules (e.g., steroid hormones and thyroxine), small hydrophilic molecules (e.g., epinephrine), gases (e.g., O_2, nitric oxide), and physical stimuli (e.g., light, touch).
- Hydrophobic signaling molecules interact with cytosolic or nuclear receptors and mainly affect gene expression.
- Binding of a hydrophilic extracellular signaling molecule to a cell-surface receptor triggers a conformational change in the receptor, which in turn leads to activation of intracellular signal transduction pathways that ultimately modulate cellular metabolism, function, or gene expression.
- Signals from one cell act on distant cells in endocrine signaling, on nearby cells in paracrine signaling, or on the signaling cell itself in autocrine signaling.
- Most receptors bind only a single type of ligand or a group of closely related ligands and with high affinity.
- Second messengers such as cAMP and Ca^{2+} are found in many signal transduction pathways.
- Protein kinases, protein phosphatases, and GTP-binding switch proteins participate in most signal transduction pathways.
- Signal transduction pathways allow amplification of an extracellular signal, enabling activation of a relatively small number of receptors to trigger major changes in cell metabolism, movements, or gene expression.
- Virtually all signal transduction pathways have feedback controls whereby an effector protein modifies and inhibits an early protein in the pathway, blocking an early step in that pathway.

15.2 Studying Cell-Surface Receptors and Signal Transduction Proteins

How a cell responds to external signals depends on the cell's complement of receptors that bind the signals as well as on the signal transduction pathways activated by these receptors. In this section, we examine experimental techniques used to characterize receptors and other signal transduction proteins. Many of these methods are also used to characterize the receptors that mediate endocytosis (see Chapter 14) or cell adhesion (see Chapter 20). We conclude the section with a discussion of techniques commonly used to measure the activity of signal transduction pathway components, such as kinases and GTP-binding switch proteins, and to study the mechanisms that regulate these signaling proteins.

Binding Assays Are Used to Detect Receptors and Determine Their Affinity and Specificity for Ligands

An experiment called a *binding assay* is used to quantify the number of receptors on a cell surface and determine how tightly they bind to a ligand (K_d). Receptors (R) are usually detected and quantified by their ability to bind ligands (L) that have been added to the fluid

surrounding intact cells, cell fragments, or purified receptors. In many experiments, the ligands are radioactively or fluorescently labeled to permit easy measurement of their binding. The ligand and receptor are allowed to incubate together until they reach equilibrium binding. Then unbound ligand is removed and the amount of ligand bound to receptors (RL) is measured — for example, by putting the sample in a machine that can detect the amount of radioactivity or fluorescence. One often measures the amount of ligand bound to the receptor at different ligand concentrations. A plot of the amount of ligand bound to the receptor [RL] versus the amount of free ligand [L], called a *ligand-binding* or *saturation curve*, can be seen in the red line in Figure 15-8. Such a plot generally follows Equation 15-4, which is simply an algebraic transformation of Equations 15-2 and 15-3.

$$[\mathrm{RL}] = \frac{R_T}{\frac{K_\mathrm{d}}{[\mathrm{L}]} + 1} \tag{15-4}$$

FIGURE 15-8 Binding assays determine the K_d and the number of receptors per cell, but the maximal physiological response to an external signal occurs when only a fraction of the receptors are occupied by ligand. In a typical experiment to determine the affinity of a receptor for a ligand, radioactively or otherwise labeled ligand is incubated with control cells that do not express the receptor of interest and with the same cells that have been altered by recombinant DNA techniques to express the receptor on their surface. Incubation is generally for an hour at 4 °C; the low temperature is used to prevent endocytosis of the cell-surface receptors. The cells are then separated from unbound ligand, usually by centrifugation and washing with buffer, and the amount of radioactivity bound to the cells is measured. Background binding by control cells is subtracted from the binding to the receptor-expressing cells, and the amount of bound ligand per cell is calculated and plotted (red curve) as a function of the ligand concentration. Note that even at relatively high ligand concentrations, the number of receptor-bound ligand molecules approaches, but does not equal, the number of cell-surface receptors. Nonetheless, by fitting of the data to Equation 15-4, one can determine that these cells express 1000 receptors for this ligand and that the K_d for binding of the ligand is 1 nM. In parallel experiments, the physiological response of the cell to increasing concentrations of ligand is also measured (blue curve). Typically, the plots of the extent of ligand binding to the receptor and of physiological response at different ligand concentrations differ. In the example shown here, 50 percent of the maximal physiological response is induced at a ligand concentration at which only 18 percent of the receptors are occupied. Likewise, 80 percent of the maximal response is induced when the

ligand concentration equals the K_d value, at which 50 percent of the receptors are occupied.

The concentration of unbound ligand ([L]) is shown on the horizontal axis, and the amount of receptor-ligand complex, usually expressed as the amount of receptor-bound ligand (RL), is shown on the vertical axis. In most cases, the absolute amount of ligand initially added into the extracellular fluid, often referred to as the *medium*, is vastly in excess of the total amount of cell-surface receptors. Thus even after some of the ligand has bound to the receptors, there is essentially no reduction in the concentration of unbound ligand in the medium. As a consequence, one can assume that the concentration of free (unbound) ligand [L] at the end of the incubation is equal to the concentration of ligand initially added to the fluid. In practice, as the concentration of ligand in the medium increases, the number of receptor-ligand complexes approaches but never actually reaches the total number of cell-surface receptors R_T (see Figure 15-8). The maximal amount of binding (B_{max}) that actually occurs is proportional to the total number of receptors present on the cells (R_T).

The maximal amount of binding (B_{max}) is one of two parameters that characterize a simple receptor-ligand binding assay, where each receptor protein has a single binding site and thus can bind only one ligand (see Equations 15-2 and 15-3 and Chapter 2). The other is the dissociation constant (K_d), which is an indication of how tightly the

ligand binds to the receptor. Note that the concentration of ligand that results in half of the receptors being bound at equilibrium ($[\mathrm{R}] = [\mathrm{R{*}L}] = 0.5 \times [\mathrm{R_T}]$) is equal to K_d (Equation 15-2). The tighter the binding of a ligand to its receptor, the lower the concentration of ligand needed to achieve binding to 50 percent of the receptors.

Computer curve-fitting programs are typically used to calculate the $\mathrm{R_T}$ and K_d values from data such as those in Figure 15-8. Using this approach, one can calculate from this binding curve that there are 1000 receptors per cell surface and that the K_d for binding this ligand is 1×10^{-9} M, or 1 nM.

Near-Maximal Cellular Response to a Signaling Molecule Usually Does Not Require Activation of All Receptors

The extent of the cellular response to a particular signaling molecule depends on the number of receptor-ligand complexes. In general, much less than 100 percent of its receptors need to be bound to the ligand to induce the maximal cellular response. One can observe this phenomenon by comparing the extent of the cellular response (blue curve in Figure 15-8) and the amount of ligand-bound receptors at different concentrations of the ligand. For example, an erythroid progenitor cell in the bone marrow has 1000 surface receptors for erythropoietin, the protein hormone that

induces these cells to proliferate and differentiate into red blood cells; the K_d for erythropoietin binding is 1 nM. But only 180 of these receptors (18 percent of the total) need to bind erythropoietin to induce 50 percent of the maximal cellular response (i.e., the division of the progenitor cell in this case). Thus the shape of the curve showing the dependence of a cellular response on ligand concentration differs from that of the curve for ligand binding (red curve in Figure 15-8). The ligand concentration needed for a cellular response that is 50 percent of the maximum is considerably lower than the K_d value.

Sensitivity of a Cell to External Signals Is Determined by the Number of Cell-Surface Receptors and Their Affinity for Ligand

Because the cellular response to a particular signaling molecule depends on the *number* of receptor-ligand complexes, the fewer receptors for a ligand present on the surface of a cell, the less *sensitive* the cell is to that ligand. As a consequence, a higher ligand concentration is necessary to induce the physiological response than would be the case if more receptors were present. Of course, if the cell has no receptors, there can be no response. In contrast, if the level of a receptor for a particular ligand is increased, the cell

will become more sensitive to the ligand. That is, fewer ligand molecules need be present to induce a response.

Epidermal growth factor (EGF), as its name implies, stimulates the proliferation of many types of epithelial cells (see Chapters 16 and 20), including those that line the ducts of the mammary gland. In about 25 percent of breast cancers, the tumor cells have elevated levels of one particular type of EGF receptor called *HER2*. The overproduction of HER2 makes the cells hypersensitive to ambient levels of EGF and related hormones. Normal levels of EGF are too low to stimulate cell proliferation, but in the presence of excess HER2, even normal levels of EGF stimulate growth of tumor cells. We will see in Chapters 16 and 25 that researchers have developed monoclonal antibodies that bind HER2 and thereby block signaling by EGF; these antibodies have proved useful in treatment of breast cancer patients whose tumors overexpress HER2.

The HER2–breast cancer connection vividly demonstrates the importance of regulating the number of receptors for a given signaling molecule. Such regulation can occur at the levels of transcription, translation, and post-translational processing. Alternatively, endocytosis can remove receptors from the cell surface, often leading to their degradation in lysosomes, reducing their numbers so much that the cellular response is effectively eliminated. As we discuss in later sections of this chapter, other mechanisms can reduce a receptor's affinity for ligand. This

reduction of a cell's sensitivity to a particular ligand, called *desensitization*, can dramatically reduce the ability of cells to respond appropriately to external signals.

Chemical Analogs of Signaling Molecules Are Used to Study Receptors and Are Widely Used as Drugs

Synthetic analogs of natural signaling molecules, including hormones, are widely used both in research on cell-surface receptors and clinically as drugs. These analogs fall into two major classes. **Agonists** mimic the function of a natural hormone by binding to its receptor and inducing the allosteric $\mathrm{LR} \rightarrow \mathrm{LR}^*$ conformational change that activates the downstream signal transduction pathway and thus the normal cellular response to the hormone. Many synthetic agonists bind much more tightly to the receptor than does the natural hormone.

In contrast, **antagonists** bind to the receptor, usually at the normal ligand-binding site, but do not induce a conformational change. As a consequence, antagonists induce no cellular response. By occupying ligand-binding sites on a receptor, an antagonist can block binding of a natural hormone (or agonist) and thus reduce the hormone's usual physiological activity. In other words, antagonists inhibit receptor signaling stimulated by the natural ligand.

Consider, for instance, the drug *isoproterenol*, one of the first epinephrine agonists used to treat asthma. Isoproterenol is made by the chemical addition of two methyl groups to epinephrine (Figure 15-9). Isoproterenol is an agonist of the epinephrine receptor (called the β_2 *adrenergic receptor*, see Section 15.4) on bronchial smooth muscle cells. The drug binds about tenfold more tightly than does epinephrine; that is, it has a tenfold lower K_d. When activated, β_2 adrenergic receptors cause bronchial smooth muscle to relax, opening the air passages in the lungs. Because of this effect, isoproterenol and other agonists that have greater affinity and greater specificity for the β_2 adrenergic receptor are used in treating bronchial asthma, chronic bronchitis, and emphysema.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 15-9 Structures of the natural hormone epinephrine, the synthetic agonist isoproterenol, and the synthetic antagonist alprenolol. As discussed in the text, isoproterenol and alprenolol, both of which bind to receptors for epinephrine, are used as drugs to treat different conditions.

A different type of epinephrine-responsive receptor is present on cardiac muscle cells (called the *β_1-adrenergic receptor*). Its activation increases the heart's contraction rate. Antagonists of this receptor, such as alprenolol (see Figure 15-9) and related compounds, are referred to as *beta-blockers*; such antagonists are used to slow heart contractions in the treatment of cardiac arrhythmias and angina. ■

Receptors Can Be Purified by Affinity Chromatography Techniques

In order to study how receptors function, it is first necessary to purify them. For example, once an investigator has a sample of a purified protein, its molecular structure with and without a bound ligand can be determined in order to elucidate the conformational changes that occur upon ligand binding. Separating integral membrane cell-surface receptors from other cellular proteins is very challenging. A typical mammalian cell can have between 1000 to 50,000 copies of a single type of cell-surface receptor. This may seem like a large number, but consider that this same cell contains $\sim 10^{10}$ total protein molecules, with $\sim 10^6$ of them in the plasma membrane alone; these receptors constitute only 0.1 to 5 percent of plasma-membrane proteins. This low abundance complicates the isolation and purification of cell-surface receptors. Purification of these integral membrane proteins is also difficult because the membrane must first be solubilized with a non-ionic detergent (see

Figure 10-23) while maintaining the three-dimensional structure of the receptor and its ability to bind ligand. Only then can the receptors be separated from other cellular molecules.

Recombinant DNA techniques can often be used to generate cells that express large amounts of receptor proteins. Even then, special techniques are necessary to isolate the receptors from other membrane proteins. A type of *affinity chromatography* is often used in purifying cell-surface receptors that retain their ligand-binding ability when they are solubilized by detergents (see Figure 3-44c). Either an antibody that recognizes the receptor or a ligand for the receptor is chemically linked to the beads used to form a column. A crude, detergent-solubilized preparation of membrane proteins is then passed through the column. Only the receptor protein, together with other proteins tightly bound to it, will stick to the column; other proteins are washed away. Once the other proteins are removed, the receptors can be released ("eluted") from the column either by passage of an excess of the soluble ligand through the column (ligand affinity chromatography) or by changing chemical conditions such as pH to release the receptor from the antibody (antibody affinity chromatography). In some cases, a receptor can be purified as much as 100,000-fold in a single affinity-chromatographic step. After purification, membrane receptors can be studied either in their detergent-soluble form or after reconstitution into membrane bilayers in vitro (see Chapter 11).

Immunoprecipitation Assays and Affinity Techniques Can Be Used to Study the Activity of Protein Kinases

Following ligand binding, receptors activate one or more signal transduction proteins that, in turn, can affect the activity of multiple target effector proteins (see Figures 15-1 and 15-3). Understanding a signaling cascade requires the researcher to be able to quantitatively measure the activity of these signal transduction proteins. As kinases are found in many signaling cascades, in this section we describe several assays used for measuring their activity.

As noted above, any particular kinase can be in an inactive form or in a partially or completely active form, depending in part on which signal transduction pathways have been activated. The amount of activity exhibited by any given kinase will depend on the amount of kinase protein present and the fraction of that kinase protein that is in the active form. Thus investigators are often interested in determining the fraction of a particular kinase protein in a cell that is enzymatically active as well as the total enzymatic activity of that kinase.

Immunoprecipitation of Kinases

Immunoprecipitation assays, a type of antibody affinity chromatography (see Figure 3-44c), are frequently used to measure the activity of a particular kinase in a cell extract. As there are hundreds of kinases in eukaryotic cells, it is necessary first to purify the kinase of interest in order to measure its enzymatic activity without interference from other kinases. In one version of the immunoprecipitation method, an antibody specific for the desired kinase is first incubated with small beads coated with protein A; this causes the antibody to bind to the beads via its Fc segment (see Figure 4-33). The beads are then mixed with an extract of the whole cell or of an organelle, such as the nucleus, then recovered by centrifugation and washed extensively with a salt solution to remove weakly bound proteins that are unlikely to be binding specifically to the antibody. Thus only cell proteins that specifically bind to the antibody — the kinase itself and proteins tightly bound to the kinase — are present on the beads.

To measure its activity, the kinase isolated on the beads is exposed to its substrates. The beads are incubated in a buffered solution with a substrate protein and γ-[^{32}P] ATP, in which only the γ phosphate of the ATP is radiolabeled. The amount of [^{32}P] transferred covalently to the substrate protein is a measure of the amount of active kinase on the beads. That amount can be determined by separating the substrate protein and measuring the substrate-associated radioactivity. For example, the substrate can be isolated by polyacrylamide gel electrophoresis followed by autoradiography to

determine the amount of covalently attached [^{32}P] (see Figure 3-42), or it can be isolated by immunoprecipitation with an antibody specific for the substrate followed by measurement of the radioactivity in the immunoprecipitate. By comparing extracts from cells before and after ligand addition, for example, whether or not a particular kinase is activated in the signal transduction pathway(s) triggered by that ligand can be readily determined.

Western Blotting with a Monoclonal Antibody Specific for a Phosphorylated Amino Acid in a Protein

We noted above that many protein molecules can be phosphorylated by more than one kinase, each kinase phosphorylating the molecule on different serine, threonine, or tyrosine residues. To understand how such protein substrates are phosphorylated and how such multiple phosphorylations influence the protein's activity and alter cell function, it is sometimes necessary to measure the extent of phosphorylation of only one of several phosphorylation sites in a specific protein, usually doing so before and after ligand addition.

Antibodies play a crucial role in detecting phosphorylation events at specific sites on the protein. It is often possible to generate an antibody that can bind to the protein of interest only when the site

of interest on the protein — the hydroxyl group on the side chain of serine, threonine, or tyrosine — has been phosphorylated. To do so, a mouse is immunized (see Chapter 24) with a small peptide, approximately 15-amino-acids long, that has the sequence of the phosphorylation site of interest and that is phosphorylated. The phosphopeptide is called an *antigen* and it is usually chemically synthesized and then coupled to an adjuvant (see Chapter 24) to increase its immunogenicity, prior to immunizing the mouse. From the immunized mouse a set of monoclonal antibodies can be generated (see Figure 4-6). Then a particular monoclonal antibody is selected that reacts *only* with the phosphorylated but not the nonphosphorylated peptide; such an antibody generally will bind to the protein only when it is phosphorylated on the particular amino acid of interest. This specificity is possible because the antibody binds simultaneously to the phosphorylated amino acid and to side chains of adjacent amino acids.

As an example of the use of such antibodies, Figure 15-10 shows that three signal transduction proteins in erythroid progenitor cells become phosphorylated on specific amino acid residues within 10 minutes of stimulation by varying concentrations of the hormone erythropoietin (Epo); phosphorylation, which is the first step in triggering the differentiation of these cells into red blood cells, increases with Epo concentration. As is described in the next chapter, each of these signal transduction proteins activates

different downstream effectors, including different transcription factors.

EXPERIMENTAL FIGURE 15-10 Activation by the hormone erythropoietin (Epo) of three signal transduction proteins via their phosphorylation. Mouse erythrocyte progenitor cells were treated for 10 minutes with different concentrations of the hormone erythropoietin (Epo). Extracts of the cells were analyzed by Western blotting with three different antibodies specific for the phosphorylated forms of three signal transduction proteins and three other antibodies that recognize a nonphosphorylated segment of amino acids in each of the same proteins. These data show that with increasing concentrations of Epo, the three proteins become phosphorylated. Treatment with 1 unit Epo/ml is sufficient to maximally phosphorylate and thus activate all three pathways. $\mathrm{Stat5} = \mathrm{transcription\ factor}$ phosphorylated on tyrosine 694; $\mathrm{Stat5} = \mathrm{protein\ kinase\ B}$ phosphorylated on serine 473; $\mathrm{p42/p44} = \mathrm{p42/p44}$ MAP kinase phosphorylated on threonine 202 and tyrosine 204.

GTP-Binding Signal Transduction Proteins Can Be Isolated and Their Activities Measured Using Pull-Down Assays

We noted that two large classes of GTPase switch proteins are used in signal transduction pathways: heterotrimeric G proteins that directly bind to and are activated by certain cell-surface receptors, and monomeric (often called *low-molecular-weight*) G proteins.

The principal assay for measuring activation of this class of proteins takes advantage of the fact that each switch protein has one or more targets to which it binds, but only when it is bound to GTP, not GDP; the target protein usually has a specific binding domain that binds to the switch segments of that GTP-bound protein. Pull-down assays used to quantify the activation of a specific GTP-binding protein are similar to immunoprecipitation assays, except that, rather than an antibody, the domain of the target protein that binds the GTP-bound GTP-binding protein is immobilized on small beads (Figure 15-11a). The beads are mixed with a cell extract; the beads bind any of the GTP-bound GTP-binding protein present in the extract; and then the beads are separated from the unbound components in the cell extract by centrifugation. The amount of the active, GTP-bound GTP-binding protein on the beads can be quantified using an antibody to the GTP-binding protein and Western blotting. Figure 15-11b shows

that in blood-forming stem cells, the fraction of the small GTPase Rac that has a bound GTP increases markedly after stimulation by the hormone platelet-derived growth factor (PDGF), indicating that Rac is a signal transduction protein activated by the PDGF receptor.

EXPERIMENTAL FIGURE 15-11 A pull-down assay shows that the small GTP-binding protein Rac is activated by platelet-derived growth factor (PDGF). Like other small GTPases, Rac regulates molecular events by cycling between an inactive GDP-bound form and an active GTP-bound form. In its active (GTP-bound) state, Rac binds specifically to the Rac binding (PBD) domain of p21-activated protein kinase (PAK1) to control downstream signaling cascades. (a) Assay principle: the Rac-binding PBD domain is generated by recombinant DNA techniques and attached to agarose beads, then mixed with cell extracts (step 1). The beads are specifically recovered by centrifugation (step 2), and the amount of GTP-bound Rac is quantified by Western blotting using an anti-Rac antibody (step 3).

(b) Western blot showing activation of Rac after treatment of blood-forming stem cells for 1 minute with the hormone platelet-derived growth factor (PDGF). A Western blot for actin serves as a control to show that the same amount of total protein is loaded on each lane of the gel.

Ghiaur et. al., 2006, "Inhibition of RhoA GTPase Activity Enhances Hematopoietic Stem and Progenitor Cell Proliferation and Engraftment," *Blood* **108**:2087–2094; permission conveyed through Copyright Clearance Center, Inc.]

Concentrations of Free Ca^{2+} in the Mitochondrial Matrix, ER, and Cytosol Can Be Measured with Targeted Fluorescent Proteins

The concentration of the second messenger Ca^{2+} changes in response to many different signal transduction systems, and such changes can influence the activities of many cellular proteins. Chapter 4 describes how the fluorescent small-molecule dye *fura-2* can be used to measure the concentration of free Ca^{2+} (Ca^{2+} not bound to proteins) in the cytosol of live cells. Fura-2 fluorescence at a certain wavelength increases when Ca^{2+} is bound. The technique depends on the fact that a chemically modified version of fura-2, in which the carboxylic acid residues are in an ester linkage, spontaneously diffuses into the cytosol from extracellular fluids. Enzymes in the cell cytosol cleave off these ester groups, forming

free fura-2 that cannot diffuse out of the cytosol and whose fluorescence reports the concentration of free Ca^{2+} in the cytosol.

Several proteins also emit light or their emitted light changes color when they bind Ca^{2+}. An advantage of these proteins is that they can be used experimentally to determine the free Ca^{2+} concentration not just in the cytosol but also within subcellular compartments. Cells can be transfected with cDNA expression vectors that encode these proteins, which have been altered to include a signal sequence that targets the protein to a particular subcellular compartment (Chapter 13).

One such protein is aequorin, a calcium-activated bioluminescent protein isolated from the hydrozoan *Aequorea victoria*. As expressed in cells by recombinant DNA technologies, aequorin consists of a protein subunit fused with a signal sequence that targets it to a specific organelle, such as the ER lumen (see Figure 13-6) or the mitochondrial intermembrane space or matrix (see Figure 13-26). Aequorin contains three EF hands (see Chapter 3) that function as binding sites for Ca^{2+}. When the small-molecule prosthetic group coelenterazine is added to the culture medium, it diffuses into the cell and binds to aequorin, and the cell emits light at a specific wavelength proportional to the concentration of free Ca^{2+} in that subcellular space.

KEY CONCEPTS OF SECTION 15.2

Studying Cell-Surface Receptors and Signal Transduction Proteins

- The concentration of ligand at which half the ligand's receptors are occupied, the dissociation constant (K_{d}), can be determined experimentally and is a measure of the affinity of the receptor for the ligand.
- The near-maximal response of a cell to a particular ligand generally occurs at ligand concentrations at which less than 100 percent of its receptors are bound to the ligand.
- Affinity chromatography techniques can be used to purify receptors even when they are present in low abundance.
- Immunoprecipitation using antibodies specific for protein kinases can be used to measure the activity of these kinases.
- Western blotting assays using antibodies specific for phosphorylated peptides can measure phosphorylation of a specific amino acid on any desired protein within a cell.
- Pull-down assays using the protein-binding domain of a target protein can be used to quantify activation of a GTP-binding protein within a cell.
- The concentration of free Ca^{2+} in a subcellular space can be measured using fura-2 or genetically engineered aequorin proteins.

15.3 Structure and Mechanism of G Protein–Coupled Receptors

In this section, we introduce the most numerous class of receptors: the G protein–coupled receptors (GPCRs). The human genome encodes about 800 functional GPCRs, which constitute about 4 percent of the identified human proteins. These detect and respond to many different types of signals, including odorants, tastants, neurotransmitters, hormones involved in glycogen and fat metabolism, growth factors, and even physical stimuli (photons of light). Many GPCRs are found primarily in cells of the central nervous system and are used in neuronal signaling, as we will learn in Chapter 23. GPCRs are of immense medical importance, as approximately 35 percent of all drugs used in humans are agonists or antagonists of GPCRs, and at last count 134 GPCRs are targets of drugs approved in the United States or the European Union. Table 15-1 describes just a few of these drugs; note the wide variety of receptors targeted by these drugs and the diverse diseases that they treat.

TABLE 15-1 • Human G Protein–Coupled Receptors of Pharmaceutical Importance

Receptor	Natural Ligand	Location	Physiological Function	Drug	Medical Use
Histamine H2 receptor	Histamine	Acid-secreting cells of the stomach	Stimulates acid secretion	Cimetidine (Tagamet) Ranitidine (Zantac) (antagonists)	Prevent acid stomach; treat peptic ulcers
Histamine H1 receptor	Histamine	Smooth muscles, vascular	Increases vascular permeability	Fexofenadine (Allegra) Loratadine	Reduce symptoms of allergy

		endothelial cells	and causes symptoms of allergy	(Claritin) (antagonists)	
Serotonin $5HT_{2A}$	Serotonin	Central nervous system	Synaptic transmission between neurons	Clozapine, risperidone (antagonists)	Treat schizophrenia
Serotonin $5HT_{1a}$	Serotonin	Central nervous system	Synaptic transmission between neurons	Buspirone (BuSpar) (agonist)	Treat depression, general anxiety disorder
Angiotensin AT_1	Angiotensin II	Vascular smooth muscle cells	Constrict blood vessels and increase blood pressure	Losartan (Cozarr) (antagonist)	Reduce hypertension
β_2-adrenergic receptor	Epinephrine	Smooth muscle cells lining the airway	Facilitate respiration	Salmeterol (Severent) (agonist)	Treatment of asthma, chronic obstructive pulmonary disease
$CysLT_1$	Leukotrienes	Lungs, bronchial tubes, mast cells	Contracts smooth muscles	Montelukast (Singulair) (antagonist)	Treatment of asthma, seasonal allergies

SOURCE: A. Wise et al., 2002, *Drug Discovery Today* **7**:235–246.

All GPCR signal transduction pathways share the following common elements: (1) a membrane-imbedded receptor that contains seven membrane-spanning α helices; (2) a heterotrimeric G protein, which functions as a receptor-activated switch by cycling between an active GTP-bound and an inactive GDP-bound state; (3) a membrane-bound effector

protein; and (4) proteins that participate in amplification and desensitization of the signaling pathway. Protein kinases and second messengers such as cAMP and Ca^{2+} often participate in GPCR-mediated signal transduction pathways. These pathways usually have short-term effects in the cell by quickly modifying the activities of existing proteins, including enzymes and ion channels. Thus these pathways allow cells to respond rapidly to a variety of signals, whether they be physical stimuli such as light or hormonal stimuli such as epinephrine.

In this section, we discuss the basic structures and mechanisms of GPCRs and their associated heterotrimeric G proteins. The following sections describe several well-understood and important examples of signal transduction pathways activated by these receptors.

All G Protein–Coupled Receptors Share the Same Basic Structure

All G protein–coupled receptors have the same orientation in the membrane and contain seven transmembrane α-helical regions (H1–H7), four extracellular segments, and four cytosolic segments (Figure 15-12). Invariably the N-terminus is on the exoplasmic face and the C-terminus is on the cytosolic face of the plasma membrane. G protein–coupled receptors are stably anchored in the hydrophobic core of the plasma membrane by the many hydrophobic amino acids on the outer surfaces of the seven membrane-spanning α-helices.

FIGURE 15-12 General structure of G protein–coupled receptors. All receptors of this type have the same orientation in the membrane and contain seven transmembrane α-helical regions (H1–H7), four extracellular segments (E1–E4), and four cytosolic segments (C1–C4). In many GPCRs a short α helix H8 lies parallel to the membrane surface, and a covalently bound palmitic acid group anchors the C-terminus to the membrane surface.

The human GPCRs are divided into several families. Members of each family are especially similar to one another in amino acid sequence and structure. The families differ from each other in the details of how ligands bind the receptors.

Figure 15-13 shows the variation in ligand-binding sites between three of the five different families of GPCRs. In family A, the largest family in mammals, segments of several membrane-embedded α helices and extracellular loops form the ligand-binding site. That site is exposed to the exoplasmic surface, but can extend down toward the middle of the membrane bilayer. Examples of family A receptors are the **β-adrenergic receptors**, which bind hormones such as epinephrine and norepinephrine (Figure 15-14a). These are some of the best studied GPCRs and are frequently used as archetypical examples of GPCRs (Figure 15-14b). As an example, in binding of epinephrine (adrenaline) to the β-adrenergic receptor, side chains of 15 amino acids

located in four transmembrane α helices and the extracellular loop E2 make noncovalent bonds with the bound ligand (Figure 15-14c); the two hydroxyl groups on epinephrine become hydrogen bonded to the hydroxyl groups on the side chains of two serine (S) residues (designated S203 and S207 in transmembrane helix #5) as well as to the side chain of an asparagine residue (N293) in transmembrane helix #6.

FIGURE 15-14 Structure of the β_2-adrenergic receptor in the inactive state and in the active state with a bound ligand and with its associated heterotrimeric G protein, G_s. (a) The three-dimensional structure of the β_2-adrenergic receptor bound to an antagonist (not shown) and thus in the inactive state. Placed next to it are the three-dimensional structures of the subunits of the heterotrimeric G protein G_s : $G_{\alpha s}$ (dark purple), G_β (light purple), and G_γ (pink), showing the inability of the resting receptor to bind to and activate $G_{\alpha s}$. (b) The overall structure of the active receptor complex shows the adrenergic receptor bound to an agonist (blue and red spheres) and engaged in extensive interactions with a segment of $G_{\alpha s}$. (c) Binding of epinephrine to the side chains of multiple amino acids in the interior of the β_2-adrenergic receptor.

[Data for parts (a) and (b) from S. Rasmussen et al., 2011, *Nature* **476**:549, PDB ID 3sn6; and V. Cherezov et al., 2007, *Science* **318**:1258, PDB ID 2rh1. Part (c) from A. M. Ring et al., 2013, *Nature* **502**:575–579 https://doi.org/10.1038/nature12572.]

The glucagon receptor is a member of family B of the GPCRs (Figure 15-13b). Its ligand *glucagon* is a 29-amino-acid peptide hormone secreted by the α cells of the pancreatic islets; as we will see later in this chapter, it acts on the liver to trigger glycogen breakdown and secretion of glucose into the bloodstream. While the glucagon receptor has the seven transmembrane α helices characteristic of GPCRs, it also has a large exoplasmic domain that is connected to the first transmembrane α helix. This exoplasmic domain binds tightly to the C-terminus of glucagon, positioning glucagon's N-terminus to bind to the pocket formed, as in β-adrenergic and other GPCRs, by residues from several transmembrane helices (Figure 15-15).

FIGURE 15-15 Structure of the glucagon receptor with a bound glycogen molecule. The seven transmembrane α helices of the glucagon receptor and the exoplasmic extension of transmembrane helix 1 are colored dark green and the N-terminal exoplasmic domain light

green. The C-terminus of the 29-amino-acid peptide glucagon (red) is bound to the exoplasmic domain of the receptor, and the glucagon N-terminus is thought to insert into a binding pocket that is in the center of the seven transmembrane α helices.

[Data from P. Siu et al., 2014, *Nature* **499**:444, custom PDB.]

The glutamate receptor is an excitatory neurotransmitter receptor in family C of GPCRs (Figure 15-13c). The long extracellular segment forms a sort of venus flytrap domain that clamps around and binds the glutamate ligand. Many members of this class of GPCRs dimerize through their venus flytrap domains.

Like most receptors, GPCRs are allosteric proteins (Chapter 3). Binding of the ligand at the extracellular surface causes a conformational change in the receptor ($R \rightarrow R^*$) that enables the cytosol-facing segment of the receptor to bind to and activate the heteromeric G protein, the next intracellular component of the GPCR signal transduction pathway — hence the name *G-protein coupled receptor*.

Ligand-Activated G Protein–Coupled Receptors Catalyze Exchange of GTP for GDP on the α Subunit of a Heterotrimeric G Protein

The first signal transduction step after the activation of GPCRs by their ligands is the activation of heterotrimeric G proteins (Figure 15-16). These G proteins contain three subunits, designated α, β, and γ. Guanine nucleotides (GTP or GDP) bind to the G_α subunit. The G_α and G_γ subunits have covalently attached fatty acids that insert into the inner leaflet of the plasma

membrane and allow the G protein subunits to be in close proximity to the GPCR. The β and γ subunits are always bound tightly together and are usually referred to as the $G_{\beta\gamma}$ *subunit*. As we see shortly, the G_α subunit dissociates and reassociates with the $G_{\beta\gamma}$ subunit, depending on its activation state.

FIGURE 15-16 General mechanism of the activation of effector proteins associated with G protein–coupled receptors. Light green denotes the inactive and dark green the active conformations of the GPCR. The G_α and $G_{\beta\gamma}$ subunits of a heterotrimeric G protein are tethered to the membrane by covalently attached lipid molecules (wiggly black lines). Following ligand binding, the receptor undergoes a conformational change enabling it to bind to the G_α subunit of the G protein, triggering dissociation of the GDP and binding of GTP, concomitant with dissociation of the $G_{\beta\gamma}$ protein subunits. In some cases (a) the free $G_\alpha \cdot GTP$ subunit diffuses in the plasma membrane and binds to and activates an effector protein. In others (b), the free $G_{\beta\gamma}$ subunit binds to and activates an ion channel or other target protein. Hydrolysis of GTP terminates signaling and leads to reassembly of the heterotrimeric G protein, returning the system to the resting state. Binding of another ligand molecule causes repetition of the cycle.

[Data from W. Weis and B. Kobilka, 2018, *Annu. Rev. Biochem.* **87**:897.]

In the resting state, when no ligand is bound to the receptor, the G_α subunit has a GDP bound to its nucleotide binding site and the G_α GDP is complexed with $G_{\beta\gamma}$, forming a heterotrimer ($^{GDP}G_\alpha G_{\beta\gamma}$). Binding of a ligand to a G protein–coupled receptor alters the conformation of its transmembrane helices and enables the receptor to bind to the G_α subunit of the intact heterotrimeric G protein containing GDP (Figures 15-14 and 15-16). The binding of epinephrine to the β-adrenergic receptor provides an example of how the change in receptor conformation allows binding to the G_α subunit. When unbound by ligand and in the inactive conformation (R), the receptor (see Figure 15-14a) has no surface that is complementary to the G protein and thus cannot bind to it. The binding of the agonist induces major conformational changes ($L + R \rightarrow LR^*$) in this receptor: there are substantial movements of transmembrane helices 5 and 6 and changes in the structure of the C3 cytosol-facing loop that connects these helices. Together, these changes create a surface that can now bind to a segment of the G_α subunit of $^{GDP}G_\alpha G_{\beta\gamma}$ (see Figure 15-14b).

Binding of the GPCR to the G_α subunit of $^{GDP}G_\alpha G_{\beta\gamma}$ induces a change in the conformation of the GDP-binding site on G_α, allowing a lobe of the protein to move and thus release the GDP. Next because of its higher concentration in the cytosol, GTP rapidly binds to the empty guanine nucleotide site in the G_α subunit. Thus the activated ligand-bound receptor functions as a guanine nucleotide exchange factor for $^{GDP}G_\alpha$.

GTP binding to G_α induces a change in the conformation of its switch segments (see Figure 15-7), leading the $^{GTP}G_\alpha$ subunit to dissociate from the $G_{\beta\gamma}$ subunit and from the GPCR. All three elements can now diffuse independently in the plane of the cytosolic face of the plasma membrane. The freed, ligand-bound, activated GPCR (LR*) is then able to activate

another ${}^{GDP}G_{\alpha}G_{\beta\gamma}$, and thus amplify the signal from the receptor-ligand complex.

In most cases the released G_{α}·GTP then mediates the next step of the signal transduction pathway. While remaining anchored in the plasma membrane, G_{α}·GTP binds to and activates a downstream effector protein (Figure 15-16a). In some cases, G_{α}·GTP inhibits, rather than activates, the effector. As we see below, there are various types of G_{α} protein subunits that interact with different receptors and effectors. In some cases (Figure 15-16b), depending on the type of cell and G protein involved, it is the $G_{\beta\gamma}$ subunit, freed from the G_{α} subunit, that transduces a signal by interacting with an effector protein. For example, *muscarinic acetylcholine receptors* are a type of GPCR found in cardiac muscle; when activated by binding acetylcholine, these receptors slow the rate of heart muscle contraction. Following receptor activation, the released $G_{\beta\gamma}$ subunit binds to and opens a K^+ channel (the effector protein) in the plasma membrane (see Figure 15-16b). The subsequent efflux of K^+ ions out of the cytosol causes an increase in the magnitude of the usual inside-negative potential across the plasma membrane that lasts for several seconds, a change that reduces muscle contraction.

In all cases, the active ${}^{GTP}G_{\alpha}$ state is relatively short-lived because the bound GTP is hydrolyzed to GDP in seconds to minutes. The hydrolysis of GTP is catalyzed by the intrinsic GTPase activity of the G_{α} subunit itself. The G_{α} subunit thus switches from the active ${}^{GTP}G_{\alpha}$ to the inactive ${}^{GDP}G_{\alpha}$ conformation that can no longer interact with downstream effector proteins but can quickly reassociate with $G_{\beta\gamma}$ forming ${}^{GDP}G_{\alpha}G_{\beta\gamma}$. The cycle is complete and ${}^{GDP}G_{\alpha}G_{\beta\gamma}$ can interact with an activated receptor (LR*) and start the process all over again.

The rate of GTP hydrolysis by $^{GTP}G_{\alpha}$ is sometimes enhanced by its binding to an effector that also functions as a GTPase-activating protein (GAP). This feedback mechanism significantly reduces the duration of effector activation and prevents the cell from overreacting. In many cases, another type of GAP protein, called a *regulator of G protein signaling (RGS)*, can accelerate GTP hydrolysis by $^{GTP}G_{\alpha}$, further reducing the time during which the $^{GTP}G_{\alpha}$ can activate its downstream effector.

Thus built-in feedback mechanisms ensure that the effector protein remains activated for only a few seconds or minutes following receptor activation. Prolonged signaling is possible only if receptors are kept continually active by ligand binding, so that these receptors can continue to activate the corresponding G protein.

Early evidence supporting the model that hydrolysis of the GTP in $^{GTP}G_{\alpha}$ (see Figure 15-16) is important for GPCR signal transduction pathways came from studies using compounds that are structurally similar to GTP, called *GTP analogues*. These compounds can bind as well as GTP to the GTP binding sites in G_{α} subunits but cannot be hydrolyzed by the intrinsic GTPase. In some of these compounds, the P–O–P phosphodiester linkage connecting the β and γ phosphates of GTP is replaced by a nonhydrolyzable $P–CH_2–P$ or P–NH–P linkage. Such a GTP analog can be added to a plasma-membrane preparation containing a particular receptor in the presence of an agonist. The nonhydrolyzable GTP analog is exchanged for GDP on G_{α}, and thus both the G_{α} protein and its associated effector protein remain activated for much longer than occurs when GTP is bound. Many investigators use a nonhydrolyzable analogue called GTP-γS for such studies.

The dissociation of heterotrimeric G proteins after binding to a GPCR can be detected in live cells. These studies have exploited the phenomenon of Förster resonance energy transfer (FRET), which changes the wavelength of emitted fluorescence when two fluorescent molecules interact (see Figure 4-23). Figure 15-17 shows how this experimental approach has demonstrated the dissociation of the $G_\alpha \cdot G_{\beta\gamma}$ complex within a few seconds after ligand addition, providing evidence for the rapid dissociation of the heterotrimeric G protein. This general experimental approach can be used to follow the formation and dissociation of other protein-protein complexes in live cells.

EXPERIMENTAL FIGURE 15-17 Activation of a G protein occurs within seconds of ligand binding to its cell-surface G protein–coupled receptor. In the amoeba *Dictyostelium discoideum*, cAMP acts as an extracellular signaling molecule that binds to and signals via a G protein–coupled receptor; cAMP is not a second messenger. Amoeba cells were engineered to express two genes encoding two fusion proteins: a G_α fused to cyan fluorescent protein (CFP) and a G_β fused to yellow fluorescent protein (YFP). CFP normally fluoresces 490-nm light; YFP, 527-nm light. (a) When CFP and YFP are close to each other, as in the resting ${}^{GDP}G_\alpha \cdot G_{\beta\gamma}$ complex, resonance energy transfer can occur between them (*left*). As a result, irradiation of resting cells with 440-nm light (which directly excites CFP but not YFP) causes emission of 527-nm (yellow) light, characteristic of YFP, because of resonance energy transfer from CFP to YFP. However, if ligand binding leads to dissociation of the G_α and $G_{\beta\gamma}$ subunits, then resonance energy transfer cannot occur. In this case, irradiation of cells at 440 nm causes emission of 490-nm (cyan) light, characteristic of CFP (*right*). (b) Plot of the emission of yellow light (527 nm) from a single transfected amoeba cell before and after addition of extracellular cAMP (arrow). The drop in yellow fluorescence, which results from the dissociation of the G_α-CFP fusion protein from the G_β-YFP fusion protein, occurs within seconds of cAMP addition.

[Data from C. Janetopoulos et al., 2001, *Science* **291**:2408.]

Some bacterial toxins contain a subunit that penetrates the plasma membrane of cells, such as those that line the small intestine, and, once in the cytosol, catalyzes a chemical modification of $G_{\alpha s}$ proteins that prevents hydrolysis of bound GTP to GDP. An important example is the toxin produced by the bacterium *Vibrio cholerae*, which causes cholera. As a result, $G_{\alpha s}$ remains in the active state, continuously activating its effector protein adenylyl cyclase (described in Section 15.4) even though no hormone is present to activate the receptor. The resulting excessive rise in the intracellular second messenger cAMP leads to the loss of electrolytes and water from these intestinal cells into the intestinal lumen, producing the watery diarrhea characteristic of infection by these bacteria. ■

Different G Proteins Are Activated by Different GPCRs and in Turn Regulate Different Effector Proteins

All effector proteins in GPCR signal transduction pathways are either membrane-bound ion channels or membrane-bound enzymes that catalyze the formation of one or more of the second messengers shown in Figure 15-9. The variations on the theme of GPCR signaling that we examine in Sections 15.4, 15.5, and 15.6 and in later chapters arise because eukaryotic genomes encode multiple G proteins with distinct activities. Humans have 21 different G_α subunits: 6 G_β subunits and 12 G_γ subunits. The 21 G_α subunits are encoded by 16 genes, several of which undergo alternative splicing. So far as is known, the different $G_{\beta\gamma}$ subunits are interchangeable in their functions, while the different G_α subunits provide specificity to the various G proteins. Thus we can refer to the entire three-subunit G protein

by the name of its α subunit. The heterotrimeric G proteins ($G_\alpha G_{\beta\gamma}$) are usually assigned to one of four classes based on the sequences of their α subunits. Table 15-2 summarizes the functions of the major classes of G proteins with different G_α subunits and the effector proteins they activate.

TABLE 15-2 • Major Classes of Mammalian Heterotrimeric G Proteins and Their Effectors[i]

G_α Class	Associated Effector	Second Messenger	Receptor Examples
$G_{\alpha s}$	Adenylyl cyclase	cAMP (increased)	β-Adrenergic (epinephrine) receptor; receptors for glucagon, serotonin, vasopressin
$G_{\alpha i}$	Adenylyl cyclase K^+ channel ($G_{\beta\gamma}$ activates effector)	cAMP (decreased) Change in membrane potential	α_2-Adrenergic receptor Muscarinic acetylcholine receptor
$G_{\alpha olf}$	Adenylyl cyclase	cAMP (increased)	Odorant receptors in nose
$G_{\alpha q}$	Phospholipase C	IP_3, DAG (increased)	α_1-Adrenergic receptor
$G_{\alpha o}$	Phospholipase C	IP_3, DAG (increased)	Acetylcholine receptor in endothelial cells
$G_{\alpha t}$	cGMP phosphodiesterase	cGMP (decreased)	Rhodopsin (light receptor) in rod cells

[i]A given G_α subclass may be associated with more than one effector protein. To date, only one major $G_{\alpha s}$ has been identified, but multiple $G_{\alpha q}$ and $G_{\alpha i}$ proteins have been described. Effector proteins commonly are regulated by G_α but in some cases by $G_{\beta\gamma}$ or the combined action of G_α and $G_{\beta\gamma}$. $IP_3 = \text{inositol 1,4,5-trisphosphate}$; $DAG = \text{1,2-diacylglycerol}$.

Analysis of GPCRs Has Identified Important Human Hormones

The GPCRs represent the largest protein family in the human genome. Approximately half of the ~800 genes encoding these proteins are thought to encode sensory receptors; of these, the majority are in the olfactory system and bind odorants (see Chapter 23).

The first GPCRs to be discovered were found by using their well-known hormone ligands as bait to fish for the corresponding receptor. Subsequently, many GPCRs were initially identified by searching genome sequences for genes whose protein coding sequences had high similarity to previously identified GPCRs (e.g., the β-adrenergic receptors and rhodopsin) and whose predicted proteins would have seven transmembrane α helices. The natural ligands for these putative receptors were not known, and so they were called *orphan receptors* — that is, putative GPCRs without known ligands. Over time, the natural ligands of some — but not all — of these have been identified. Many of the remaining orphan receptors are likely to bind signaling molecules that have not yet been identified, including novel peptide hormones.

One approach that has proved fruitful in identifying the ligands of orphan GPCRs involves expressing the gene encoding the receptor in transfected cells and using the cells as a reporter system to detect substances in tissue extracts that activate the receptor and its downstream signal transduction pathway. This approach led to the discovery of two novel peptides, termed *orexin-A* and *orexin-B* (from the Greek *orexis*, meaning "appetite"), that were identified as the ligands for two orphan GPCRs that are members of the B family of GPCRs that includes the glucagon receptor (see Figure 15-13b).

Further research showed that the *orexin* gene is expressed only in the hypothalamus, the part of the brain that regulates feeding. Injection of orexin into the brain ventricles of animals caused them to eat more, and expression of the *orexin* gene increased markedly during fasting. Both of these findings are consistent with orexin having a role in increasing appetite. Strikingly, mice deficient in orexins suffer from narcolepsy, a disorder characterized in humans by excessive daytime sleepiness (in mice, which are nocturnal, nighttime sleepiness). Moreover, recent reports suggest that the orexin system is dysfunctional in a majority of human narcolepsy patients: orexin peptides cannot be detected in their cerebrospinal fluid (although there is no evidence of mutation in their *orexin* genes). These findings firmly link orexin neuropeptides and their receptors to both feeding behavior and sleep in humans and other animals. They also illustrate the importance of GPCRs in human physiology.

KEY CONCEPTS OF SECTION 15.3

Structure and Mechanism of G Protein–Coupled Receptors

- G protein–coupled receptors (GPCRs) are a large and diverse group of proteins with a common structure of seven membrane-spanning α helices and an internal ligand-binding pocket that is specific for particular ligands.
- Different families of GPCRs bind their ligands in different manners, but binding always alters receptor conformation so that it is able to bind to and activate a G protein.
- GPCRs are coupled to heterotrimeric G proteins, which contain three subunits designated α, β, and γ. The G_α subunit is a GTPase switch protein that alternates between an active (“on”) state with bound GTP and inactive (“off”) state with bound GDP. The “on” form dissociates from the β and γ subunits and activates a membrane-bound effector. The β and γ subunits remain bound together and in some cases activate an effector.
- Ligand binding causes a conformational change in certain membrane-spanning helices and intracellular loops of the GPCR, allowing it to bind to its coupled G_α subunit and function as a guanine nucleotide exchange factor (GEF), catalyzing dissociation of GDP and allowing GTP to bind. The resulting change in the conformation of the switch region in G_α causes it to dissociate from the $G_{\beta\gamma}$ subunit and the receptor and interact with an effector protein.

- Signaling is terminated when the GTP bound to the G_α subunit is hydrolyzed to GDP, triggering reassociation of G_α with $G_{\beta\gamma}$.
- FRET experiments demonstrate receptor-mediated dissociation of coupled G_α and $G_{\beta\gamma}$ subunits in live cells.
- The effector proteins activated (or inactivated) by heterotrimeric G proteins are either enzymes that form second messengers (e.g., adenylyl cyclase, phospholipase C) or ion channels. In each case, it is the G_α subunit that determines the function of the G protein and affords its specificity.
- GPCRs can have a range of cellular effects depending on the subtype of receptor that binds a ligand. The hormone epinephrine, for example, which mediates the fight-or-flight response, binds to multiple subtypes of GPCRs in multiple cell types, with varying physiological effects.
- Efforts to de-orphan GPCRs led to the discovery of orexins, hormones that regulate feeding behavior and sleep in both animals and humans.

15.4 Regulating Metabolism of Many Cells: G Protein–Coupled Receptors That Activate or Inhibit Adenylyl Cyclase

To illustrate the importance of GPCRs in human metabolism and physiology, in this section we consider a GPCR that is activated by the hormone **epinephrine**. Epinephrine is particularly important in mediating the body's response to stress, also known as the *fight-or-flight response*. During moments of fear or heavy exercise, when the need for energy may increase, epinephrine (or its derivative, norepinephrine) is released by the adrenal gland. This hormone binds to β_2-adrenergic receptors on the surfaces of hepatic (liver) and adipose (fat) cells, and induces these target cells to rapidly break down either glycogen to glucose (liver) or triacylglycerols to fatty acids (fat). Within seconds of their generation, these metabolic fuels are secreted into the blood and taken up by muscle and other cells, which use them to generate ATP.

The activated β_2-adrenergic receptor induces GDP $\rightarrow$ GTP exchange on a *stimulatory* G protein (G_s). The released GTP-bound alpha subunit ($^{GTP}G_{\alpha s}$) activates a membrane-bound effector enzyme called **adenylyl cyclase** (see Figures 15-16 and 15-18). Once activated, this enzyme catalyzes synthesis from ATP of the second messenger cAMP, which is able to diffuse throughout the cell

(Figure 15-18). cAMP activates a specific protein kinase, called *protein kinase A (PKA)*, that in turn phosphorylates effector proteins that mediate the diverse metabolic effects in different cells.

FIGURE 15-18 Synthesis of cAMP by adenylyl cyclase and hydrolysis of cAMP by cAMP phosphodiesterase (PDE). Similar reactions occur for production of cGMP from GTP and hydrolysis of cGMP.

In mammals, more than 30 different GPCRs activate G_s and adenylyl cyclase; most cell types express one or more such GPCRs. Early studies of the mechanism of activation of adenylyl cyclase led to the discovery of the role of the first GTP-binding protein in receptor signaling and to a Nobel Prize.

Adenylyl Cyclase Is Stimulated and Inhibited by Different Receptor-Ligand Complexes

To explore the GPCR $\rightarrow$ cAMP pathways, we focus on an important metabolic pathway: the generation of glucose-1-phosphate from *glycogen*, a storage polymer of glucose (Figure 15-19). The breakdown of glycogen (*glycogenolysis*) is a principal way in which glucose is made available to cells in need of energy. Glycogen breakdown occurs in muscle and liver cells in response to hormones

such as epinephrine and the polypeptide hormone glucagon. This example shows how activation of a GPCR can stimulate or inhibit several intracellular enzymes, all coordinated to carry out a physiologically important task: glycogen metabolism.

FIGURE 15-19 Synthesis and degradation of glycogen. Incorporation of glucose from UDP-glucose into glycogen is catalyzed by glycogen synthase. Removal of glucose units from glycogen is catalyzed by glycogen phosphorylase. Because two different enzymes catalyze the formation and the degradation of glycogen, the two reactions can be independently regulated.

In case of sudden danger, epinephrine is released by the adrenal glands. When body demand for glucose is high, such as when blood

sugar is low (hypoglycemia) or during exercise, glucagon is released by the α cells of the pancreatic islets. Epinephrine and glucagon bind to different G protein–coupled receptors — the β_2-adrenergic receptor and the glucagon receptor, respectively — but both receptors activate the same G_s protein, whose $^{GTP}G_{\alpha s}$ activates adenylyl cyclase. Hence both hormones induce the same metabolic responses.

Regulation of adenylyl cyclase activity, which occurs in many cell types, provides fine-tuned control of the cAMP level and thus of the downstream cellular response (Figure 15-20). Whereas epinephrine and glucagon activate adenylyl cyclase, other GCPR ligands may inhibit it. For example, binding of two other hormones, prostaglandin E_1 (PGE_1) and adenosine, to their respective G protein–coupled receptors activates the inhibitory G_i protein, whose active $^{GTP}G_{\alpha i}$ subunit binds to and inhibits adenylyl cyclase, lowering cAMP levels and shutting off cellular responses.

FIGURE 15-20 Hormone-induced activation and inhibition of adenylyl cyclase in adipose cells. Ligand binding to G_s-coupled receptors causes activation of adenylyl cyclase, whereas ligand binding to G_i-coupled receptors causes inhibition of the enzyme. The $G_{\beta\gamma}$ subunit in stimulatory and in inhibitory G proteins is identical; the G_α subunits and their corresponding receptors differ. Active $G_\alpha \cdot GTP$ complexes are formed by the same mechanism in both $G_{\alpha s}$ and $G_{\alpha i}$ proteins (see Figure 15-16). However, $G_{\alpha s} \cdot GTP$ and $G_{\alpha i} \cdot GTP$ interact differently with adenylyl cyclase, so that one stimulates and the other inhibits its catalytic activity. See A. G. Gilman, 1984, *Cell* **36**:577.

cAMP Activates Protein Kinase A by Releasing Its Inhibitory Subunits

The second messenger cAMP, synthesized by adenylyl cyclase, is a component of many different signal transduction pathways initiated by different receptor-ligand complexes and leading to distinct cellular responses in different cell types in multicellular animals. Virtually all of the diverse effects of cAMP are mediated through its

activation of *protein kinase A (PKA)*, also called *cAMP-dependent protein kinase*. This protein kinase phosphorylates multiple intracellular target proteins expressed in different cell types.

Inactive PKA is a tetramer consisting of two regulatory (R) subunits and two catalytic (C) subunits (Figure 15-21a). Each of the two R subunits in an R_2 dimer has two cAMP-binding domains, called *CNB-A* and *CNB-B*, as well as a linker domain of unknown structure. At the C-terminus there is a dimerization domain that binds an AKAP protein discussed later. A segment of the CNB-A domain of the R subunit is a *pseudosubstrate*; its sequence resembles that of a peptide substrate and binds to the active site in the catalytic domain but is not phosphorylated. In the absence of cAMP the pseudosubstrate segment binds to this catalytic site and inhibits its activity.

FIGURE 15-21 Structure of PKA and its activation by cAMP. (a) PKA consists of two regulatory (R) subunits (blue) and two catalytic (C) subunits (pink). The two R subunits form a dimer, joined by a flexible linker and a dimerization/docking domain to which an A kinase–associated protein (AKAP; see Figure 15-25) can bind. Each R subunit has two cAMP-binding domains, CNB-A and CNB-B. In the absence of cAMP, the CNB-A domain of an R subunit binds to the catalytic site of a C subunit, inhibiting its activity. Binding of cAMP causes a conformational change in the CNB-A domain so that it can no longer bind to and inhibit the catalytic subunit, instantly activating its kinase activity. (b) Binding of cAMP to the CNB-A domain causes a subtle conformational change that displaces the C subunit from the R subunit, leading to kinase activation. Without bound cAMP, one loop of the CNB-A domain (purple) is in a conformation that can bind the catalytic (C) subunit. A glutamate (E200) and arginine (R209) residue participate

in binding of cAMP (red), which causes the conformational change (green) in the loop that prevents binding of the loop to the C subunit.

[Data from C. Kim, N. H. Xuong, and S. S. Taylor, 2005, *Science* **307**:690, PDB ID 1u7e.]

Inactive PKA is turned on by elevations in the cAMP level. Binding of cAMP to the CNB-A domain causes a change in its conformation so that it can no longer bind to and inhibit the catalytic subunit (Figure 15-21b); this releases the C subunit, instantly activating its kinase activity. cAMP binds to an R subunit of PKA in a cooperative fashion; that is, binding of the first cAMP molecule to CNB-B lowers the K_d of CNB-A, and thus the binding of one cAMP stimulates the binding of the second cAMP and release of the R subunit from the kinase. Thus small changes in the level of cytosolic cAMP can cause relatively large changes in the number of dissociated active C subunits and, hence, in kinase activity. We will see that rapid activation of enzymes by signal-triggered dissociation of an inhibitor is a common feature of many signaling pathways.

Glycogen Catabolism Is Stimulated by Hormone-Induced Activation of PKA

Like all biopolymers, glycogen is synthesized by and degraded by distinct enzymes (see Figure 15-19). Glycogen degradation (glycogenolysis) involves the stepwise removal of single glucose residues from one end of the polymer, whereas glycogen synthesis

(glycogenesis) involves the stepwise addition of single glucose residues. The enzyme *glycogen phosphorylase (GP)* catalyzes the degradation of glycogen via a phosphorolysis reaction yielding glucose-1-phosphate and a polymer shorter by one residue. The enzyme *glycogen synthase (GS)* uses UDP-glucose and glycogen as substrates to generate glycogen that is one residue longer $(n + 1)$.

In both muscle and liver cells, glucose-1-phosphate produced by glycogen degradation is converted by the enzyme *phosphoglucomutase* to glucose-6-phosphate. In muscle cells, glucose-6-phosphate enters the glycolytic pathway and is metabolized to generate ATP for use in powering muscle contraction (see Chapters 12 and 17). Unlike muscle cells, liver cells contain a phosphatase that hydrolyzes glucose-6-phosphate to glucose, which is exported from these cells in part by a glucose transporter (GLUT2) in the plasma membrane (see Chapter 11). Thus glycogen stores in the liver are primarily broken down to glucose, which is immediately released into the blood and transported to other tissues, particularly the muscles and brain, to nourish them. Glycogen breakdown is induced in both types of cells by increases in blood epinephrine, and hence activation of its GPCRs, as part of the fight-or-flight response.

Now we can see the final steps in the signaling pathway leading to the cellular response: glycogen breakdown. Activated PKA enhances the conversion of glycogen to glucose-1-phosphate in two ways: by

inhibiting glycogen synthesis and by *stimulating* glycogen degradation (Figure 15-22a). PKA directly phosphorylates and, in so doing, *inactivates* glycogen synthase (GS). PKA promotes glycogen degradation indirectly by phosphorylating and thus activating an intermediate kinase, glycogen phosphorylase kinase (GPK). In turn, active GPK phosphorylates and activates GP, the enzyme that degrades glycogen.

FIGURE 15-22 Regulation of glycogen metabolism by cAMP and PKA. Active enzymes are highlighted in black; inactive forms, in gray. (a) An increase in cytosolic cAMP activates PKA, which phosphorylates glycogen synthase (GS), inhibiting its catalytic activity to synthesize glycogen. Active PKA also promotes glycogen degradation via a protein kinase cascade that activates glycogen phosphorylase, the enzyme that removes glucose moieties from glycogen (Figure 15-19). At high cAMP concentrations, PKA also phosphorylates an inhibitor of phosphoprotein phosphatase (PP). Binding of the phosphorylated inhibitor to PP prevents this phosphatase from de-phosphorylating the activated enzymes in the glycogen phosphorylase kinase cascade or the inactive glycogen synthase. (b) A decrease in cAMP

inactivates PKA, leading to release of the active form of PP. The activation of PP promotes glycogen synthesis and inhibits glycogen degradation.

The GPK in skeletal muscle is a huge protein with multiple subunits. One subunit contains the kinase catalytic activity that activates GP and the other subunits are regulatory. One of the regulatory subunits is the ubiquitous protein *calmodulin*, which has four calcium ion binding sites (see Figure 3-34). In muscle, rises in the level of cytosolic Ca^{2+} trigger contraction and also an enhancement of glycogen breakdown to generate the ATP to power contraction. Two of the regulatory subunits contain phosphorylation sites for PKA. GPK enzyme activity is increased either by phosphorylation of these two regulatory subunits by PKA or by Ca^{2+} binding to the calmodulin subunit; maximal activity requires both.

Activated PKA enhances the conversion of glycogen to glucose-1-phosphate in yet a third way. The activities of GPK and GP are inhibited by a phosphatase called *phosphoprotein phosphatase (PP)*, which removes the phosphates added by PKA. In contrast, the activity of GS is increased when it is de-phosphorylated by PP. To prevent these reactions from happening, at high cAMP levels PKA phosphorylates an inhibitor of phosphoprotein phosphatase (IP), which enables it to bind to and keep this phosphatase in its inactive state (see Figure 15-22a). By this means, GPK, GP, and GS remain in their phosphorylated states, promoting glycogen breakdown.

The entire process is reversed when epinephrine or another hormone activating $G_{\alpha s}$, such as glucagon, is removed and the level of cAMP drops, inactivating PKA. When PKA is inactive, it can no longer phosphorylate IP, the inhibitor of phosphoprotein phosphatase, so the inhibitor is released and PP becomes active (Figure 15-22b). PP removes the phosphate residues previously added by PKA to GS and GPK, as well as the phosphates on GP added by GPK. As a consequence, GS becomes activated and the synthesis of glycogen by GS is enhanced. Conversely, GP becomes inactivated, and the degradation of glycogen by GP is inhibited. Thus less glucose-6-phosphate or glucose is produced.

Whether induced by epinephrine or glucagon, glycogen breakdown thus exhibits dual regulation: activation of the enzymes catalyzing glycogen degradation and inhibition of enzymes promoting glycogen synthesis. Such dual regulation is an efficient mechanism for regulating a particular cellular response and is a common phenomenon in cell biology.

Signal Amplification Occurs in the cAMP-PKA Glycogen Degradation Pathway

Receptors such as the β-adrenergic receptor are low in abundance; typically only a few hundred or a thousand copies are present in a

cell. Yet the cellular responses induced by a hormone such as epinephrine can require production of large numbers of cAMP and activated enzyme molecules per cell. As an example, following activation of G_s-coupled receptors, the intracellular concentration of cAMP must rise to about 10^{-6} M to induce appropriate cellular responses. In a typical cell that is roughly a cube about 15 μm on a side, this concentration is equivalent to 2 million molecules of cAMP per cell. Thus substantial amplification (10^2–10^3-fold) of the signal is necessary if it is to induce a significant cellular response.

Signal amplification is possible in part because both receptors and G proteins can diffuse rapidly in the plane of the plasma membrane. A single epinephrine-GPCR complex converts up to a hundred inactive G_s molecules to the active ${}^{GTP}G_{\alpha s}$ form before epinephrine dissociates from the receptor. Each active ${}^{GTP}G_{\alpha s}$, in turn, activates a single adenylyl cyclase molecule, but that adenylyl cyclase molecule then catalyzes the synthesis of many cAMP molecules during the time ${}^{GTP}G_{\alpha s}$ is bound to it.

The degree of amplification that occurs in such a signal transduction cascade depends on the number of steps in it and on the relative concentrations of its various components. In the epinephrine-induced cascade shown in Figure 15-23, for example, blood levels of epinephrine as low as 10^{-10} M can stimulate glycogenolysis in the liver and release of glucose. An epinephrine stimulus of this magnitude generates an intracellular cAMP concentration of

10^{-6} M, an amplification of 10^4-fold. Because three more catalytic steps precede the release of glucose, another 10^4 amplification can occur, resulting in a 10^8 amplification of the epinephrine signal.

FIGURE 15-23 Amplification of an extracellular signal by a signal transduction pathway involving cAMP and PKA. Binding of a single epinephrine molecule to one G protein–coupled receptor induces activation of many molecules of adenylyl cyclase, the enzyme that catalyzes the synthesis of cyclic AMP, and each of these enzyme molecules synthesizes a large number of cAMP molecules, the first level of amplification. Two molecules of cAMP activate one PKA, but each activated PKA phosphorylates and activates multiple target proteins. This second level of amplification involves several sequential reactions in which the product of one reaction activates the enzyme catalyzing the next reaction. The more steps in such a cascade, the greater the signal amplification possible.

cAMP-Mediated Activation of PKA Produces Diverse Responses in Different Cell Types

Epinephrine also induces the activation of PKA in adipose cells. In these cells, PKA promotes phosphorylation and activation of the lipase that hydrolyzes stored triglycerides to yield free fatty acids and glycerol. These fatty acids are released into the blood and taken up as an energy source by cells in other tissues, such as the kidney, heart, and muscles (see Chapter 12). Therefore, activation of PKA by epinephrine in two different cell types, liver and adipose cells, has different effects. Indeed, cAMP and PKA mediate a large array of hormone-induced cellular responses in multiple tissues (Table 15-3).

TABLE 15-3 • Cellular Responses to Hormone-Induced Rise in cAMP in Various Tissues[ii]

Tissue	Hormone Inducing Rise in cAMP	Cellular Response
Adipose	Epinephrine; ACTH; glucagon	Increase in hydrolysis of triglyceride; decrease in amino acid uptake
Liver	Epinephrine; norepinephrine; glucagon	Increase in conversion of glycogen to glucose; inhibition of glycogen synthesis; increase in amino acid uptake; increase in gluconeogenesis (synthesis of glucose from amino acids)
Ovarian	FSH; LH	Increase in synthesis of estrogen, progesterone

follicle		
Adrenal cortex	ACTH	Increase in synthesis of aldosterone, cortisol
Cardiac muscle	Epinephrine	Increase in contraction rate
Thyroid gland	TSH	Secretion of thyroxine
Bone	Parathyroid hormone	Increase in resorption of calcium from bone
Skeletal muscle	Epinephrine	Conversion of glycogen to glucose-1-phosphate
Intestine	Epinephrine	Fluid secretion
Kidney	Vasopressin	Resorption of water
Blood platelets	Prostaglandin I	Inhibition of aggregation and secretion

[ii]Nearly all the effects of cAMP are mediated through PKA, which is activated by binding of cAMP.
SOURCE: E. W. Sutherland, 1972, *Science* **177**:401.

Although PKA acts on different substrates in different types of cells, it always phosphorylates a serine or threonine residue that is located within the common sequence motif: X-Arg-(Arg/Lys)-X-(Ser/Thr)-Φ, where X denotes any amino acid and Φ denotes a hydrophobic amino acid. The Ser or Thr whose side chain is phosphorylated is underlined. Thus many potential protein targets of PKA can be

identified simply by analyzing their amino acid sequence. Other serine/threonine kinases phosphorylate target residues within other sequence motifs, and thus their potential targets can often be predicted as well. Some kinases recognize additional structural and sequence motifs in their targets in addition to the sequence adjacent to the residue to be phosphorylated. In these cases, analysis of the primary amino acid sequence of the protein may not predict whether or not it is a substrate of such kinases.

CREB Links cAMP and PKA to Activation of Gene Transcription

Activation of PKA also stimulates the expression of many genes, leading to long-term effects on cells. For instance, in liver cells, PKA induces the expression of several enzymes involved in *gluconeogenesis* — the conversion of three-carbon compounds such as pyruvate (see Figure 12-3) to glucose. The expression of these genes thus leads to an increase in the concentration of glucose in the blood, thereby enhancing the rapid effects of activated PKA seen in Figure 15-22a.

The promoter or enhancer segments of all genes regulated by PKA contain a cis-acting DNA sequence, the *cAMP-response element (CRE)*, which contains the highly conserved nucleotide sequence, 5′-TGACGTCA-3′. Following the elevation of cAMP levels and the

release of active PKA catalytic subunits, some of the catalytic subunits move into the nucleus. There they phosphorylate serine-133 on a transcription factor called *CRE-binding (CREB) protein*. Phosphorylated CREB binds to CRE-containing target genes and also binds to the *co-activator* termed *CBP/P300* (see Figure 8-26). CBP/P300 links CREB to RNA polymerase II and other gene regulatory proteins, thereby stimulating gene transcription (Figure 15-24).

FIGURE 15-24 Activation of CREB transcription factor following ligand binding to $G_{\alpha s}$-coupled GPCRs. Receptor stimulation (step 1) leads to activation of PKA (step 2). Catalytic subunits of PKA translocate to the

nucleus (step 3) and there phosphorylate and activate the CREB transcription factor (step 4). Phosphorylated CREB associates with the co-activator CBP/P300 (step 5) and other proteins to stimulate transcription of the various target genes controlled by a CRE regulatory element. See K. A. Lee and N. Masson, 1993, *Biochim. Biophys. Acta* **1174**:221; and D. Parker et al., 1996, *Mol. Cell Biol.* **16**(2):694.

Anchoring Proteins Localize Effects of cAMP to Specific Regions of the Cell

In many cell types, a rise in the cAMP level may produce a response that is required in one part of the cell but is unneeded, or perhaps deleterious, in another. Anchoring proteins confine members of the PKA family to specific locations in the cell, thereby restricting cAMP-dependent responses to these locations. Each of the roughly 50 anchoring proteins, referred to as *A kinase–associated proteins (AKAPs)*, has a two-domain structure: one domain confers a specific subcellular location by binding to a protein found only in a specific subcompartment, and the other binds to the regulatory (R) subunit of PKA. AKAPs regulate cAMP and PKA signaling within the cell both spatially and temporally.

One AKAP in heart muscle anchors PKA to the outer nuclear membrane (Figure 15-25). From this location, the released, catalytically active C subunits readily enter the nucleus, where they

phosphorylate and activate the CREB transcription factor (see Figure 15-24).

FIGURE 15-25 Localization of PKA and cAMP phosphodiesterase (PDE) to the nuclear membrane in heart muscle by an A kinase–associated protein (AKAP). This member of the AKAP family, designated mAKAP, anchors both PDE and the regulatory subunit (R, see Figure 15-21a) of PKA to the cytosolic surface of the outer nuclear membrane, maintaining them in a negative feedback loop that closely controls the cAMP level and PKA activity in this local segment of the cell. Step **1**: The basal level of PDE activity in the absence of hormone (resting state) keeps cAMP levels below those necessary for PKA activation. Steps **2** and **3**: Activation of β-adrenergic receptors causes an increase in cAMP to a level in excess of that which can be degraded by PDE. The resulting binding of cAMP to the R subunits of PKA releases the active catalytic (C) subunits into the cytosol. Some C subunits enter the nucleus, where they phosphorylate and thus activate the transcription factor CREB (see Figure 15-24). C subunits also phosphorylate PDE, stimulating its catalytic activity. Active PDE hydrolyzes cAMP, thereby driving cAMP levels back to basal levels and causing re-formation of the inactive PKA C-R complex. Step **4**: Subsequent de-phosphorylation of PDE returns the complex to the resting state. See K. L. Dodge et al., 2001, *EMBO J.* **20**:1921.

Also anchored to the same AKAP is cAMP phosphodiesterase (PDE), the enzyme that hydrolyzes cAMP to AMP (see Figure 15-18). The anchoring of PKA and PDE to the same AKAP keeps these two

proteins in close proximity, where the action of PDE confines the activity of PKA to short local bursts. The cAMP concentration and hence local PKA activity is tightly controlled by negative feedback. As cAMP levels rise in response to hormone stimulation, PKA becomes activated and then phosphorylates and activates several target proteins, including PDE. The now active PDE, in turn, hydrolyzes cAMP, thus quickly returning PKA to its inactive state and allowing only a short burst of PKA activity.

In certain heart muscle cells, a different AKAP is tethered to the cytosolic face of the plasma membrane near a particular type of gated Ca^{2+} channel. In the heart, these channels open in response to activation of β-adrenergic receptors by epinephrine (as part of the fight-or-flight response). The resulting influx of Ca^{2+} increases the rate of heart muscle contraction. These Ca^{2+} channels open when phosphorylated by PKA. The binding of AKAP to PKA localizes the kinase next to these channels, thereby reducing the time that would otherwise be required for PKA catalytic subunits to diffuse from their sites of generation to their Ca^{2+}-channel substrates.

Multiple Feedback Mechanisms Suppress Signaling by the GPCR/cAMP/PKA Pathway

In Section 15.1 we stressed that, for cells to respond effectively to a hormone or to other changes in their environment, they must not only activate a signal transduction pathway, but also reduce or terminate the response once it is no longer needed; otherwise, signal transduction pathways would remain "on" too long, or at too high a level, and the cell would become overstimulated.

The activity of most G protein–coupled receptors is reduced or even totally inhibited by multiple feedback mechanisms, as is exemplified by β-adrenergic and other receptors that are coupled to G_s and that activate adenylyl cyclase.

- First, the intrinsic GTPase activity of $G_{\alpha s}$ converts bound GTP to GDP, thereby terminating the ability of $G_{\alpha s}$ to activate its downstream target adenylyl cyclase. Importantly, the rate of hydrolysis of GTP bound to $G_{\alpha s}$ is enhanced when ${}^{GTP}G_{s\alpha}$ binds to adenylyl cyclase. Thus the downstream effector adenylyl cyclase also functions as a GAP for ${}^{GTP}G_{s\alpha}$, increasing the rate of inactivation of ${}^{GTP}G_{s\alpha}$ and so lessening the duration of cAMP production. More generally, many effector proteins of G_α subunits are also GAPs — the binding of most, if not all, ${}^{GTP}G_\alpha$'s to their respective effector proteins accelerates the rate of GTP hydrolysis.
- Second, PDE (see Figure 15-18) acts to hydrolyze cAMP to 5′-AMP, terminating the cellular response. Thus the hormone must be continuously present at a sufficient concentration in order to keep adenylyl cyclase activated and maintain an

elevated cAMP level. Once the extracellular hormone concentration falls sufficiently, the cAMP level falls due to PDE action and most cAMP-dependent rapid cellular responses quickly wane.

- Most GPCRs are down-regulated by *feedback repression*, in which an end product of a signaling pathway blocks an early step in that pathway. For instance, when a G_s protein–coupled receptor is exposed to hormonal stimulation for even short periods of time — seconds to minutes depending on the receptor — active PKA phosphorylates several serine and threonine residues typically in the third cytoplasmic loop or the C-terminal cytosol-facing tail domain of the receptor. The phosphorylated receptor can bind its ligand, but because these cytosolic domains participates in binding to the $G_{\alpha s}$ subunit, the receptor is less able to activate G_s. In other words, ligand bound to the phosphorylated receptor is less efficient in activating adenylyl cyclase than is ligand bound to the nonphosphorylated receptor. Because the activity of PKA is enhanced by the high cAMP level induced by any hormone that activates G_s, prolonged exposure to one such hormone — say, epinephrine — desensitizes not only β-adrenergic receptors, but also other $G_{\alpha s}$–coupled receptors that are phosphorylated by PKA, even though they bind different ligands (e.g., glucagon receptors in the liver). This cross-regulation is called *heterologous desensitization*.

A second type of phosphorylation-mediated feedback control occurs only when the GPCR is in its ligand-bound, activated conformation (R*). In the R*, but not R, conformation, serine and threonine

residues in the third cytoplasmic loop or the C-terminal cytosol-facing domain of the receptor can be phosphorylated by a special group of kinases called *G-protein–coupled receptor kinases (GRKs)* (Figure 15-26a, b). GRKs recognize the subtle conformational differences between R and R* and phosphorylate only the active R* conformation. The longer the receptor remains in its active state, the greater the extent of its phosphorylation by GRKs. Importantly, the greater the extent of the phosphorylation by a GRK, the lower the ability of the receptor to activate the downstream G protein. This process is termed *homologous desensitization* because a ligand can only induce the deactivating phosphorylation of receptors to which it is bound — those in the R* conformation. Unlike what happens in heterologous desensitization, a ligand cannot induce the phosphorylation by GRK of a receptor to which it cannot bind.

FIGURE 15-26 Binding of β-arrestin to phosphorylated GPCRs triggers receptor desensitization as well as activation of different signal transduction proteins. (a) A G-protein–coupled receptor kinase (GRK) phosphorylates serine and threonine residues in the cytoplasmic segments of activated G protein–coupled receptors (GPCRs), those that have bound agonists (step 1). β-Arrestin (Arr) then binds to these phosphorylated receptors (step 2). Steps 3 and 4: Clathrin and AP2, two other proteins bound by β-arrestin, promote endocytosis of the receptor (see Figure 14-29). β-Arrestin also functions in transducing signals from activated receptors by binding to and activating several cytosolic protein kinases. One such kinase, Src, activates the MAP kinase pathway that, as detailed in the next chapter, leads to phosphorylation and activation of key transcription factors. (b)

Three-dimensional structure of the GPCR rhodopsin bound to arrestin. Arrestin binds to segments of the C-terminal cytosolic alpha helix of activated rhodopsin that includes the two phosphorylated resides as well as to parts of transmembrane helix 7.

[Part (a) Data from W. Weis and B. Kobilka, 2018, *Annu. Rev. Biochem.* **87**:897. Part (b) Data from Y. Kang et al., 2015, *Nature* **523**:561–567, PDB ID 4zwj, and custom PDB.]

An important breakthrough in understanding the control of GPCR-mediated signal transduction came with the discovery of adapter proteins called *arrestins*. Arrestins bind tightly to GPCRs only when these receptors have been phosphorylated by GRKs on two or three of the serine residues in the cytosol facing C-terminal domain (see Figure 15-26a, step **2**). Arrestin binding can dramatically speed up the inactivation process. Arrestin bound to the phosphorylated receptor completely prevents its interaction with a G protein, blocking formation of the active $^{GTP}G_{\alpha}$ and preventing further downstream signaling. Eventually, phosphatase enzymes remove the phosphates added by a GRK and prevent arrestin binding, restoring the receptor to its original, hormone-sensitive state.

Another function of arrestin is to help terminate the signal by reducing the numbers of activated GPCRs on the cell surface. Subsequent studies revealed that β-arrestin binds not only to phosphorylated GPCRs, but also to clathrin and an associated protein termed *AP2*, two key components of the coated vesicles that are involved in endocytosis from the plasma membrane (see Figure 15-26a, steps **3** and **4**; see also Chapter 14). These interactions promote the endocytosis of the associated receptors, thereby

decreasing the number of receptors exposed on the cell surface. Eventually some of the receptors that have been moved inside the cell are degraded, and some are de-phosphorylated in endosomes. Following dissociation of β-arrestin, the resensitized, de-phosphorylated GPCRs are recycled to the cell surface in a manner similar to the recycling of the LDL receptor (see Chapter 14).

In addition to their role in regulating receptor activity, arrestins bound to the phosphorylated GPCR can function as adapter proteins that recruit additional downstream signaling proteins to the GPCR. As a consequence, the GPCR can initiate a second signal transduction pathway that is independent of G proteins. The GPCR-arrestin complex acts as a scaffold for the binding and activation of several cytosolic kinases (see Figure 15-26a, step **4**), which we discuss in detail in subsequent chapters. These kinases include Src, a protein tyrosine kinase that activates the MAP kinase pathway and other pathways leading to the transcription of genes needed for cell division (see Chapters 16 and 19).

Thus the phosphorylation of GPCRs by GRK followed by arrestin binding can function as a switch, turning off signaling by G proteins and turning on other signaling pathways. The multiple functions of arrestins illustrate the importance of adapter proteins in both regulating signaling and transducing signals from cell-surface receptors.

KEY CONCEPTS OF SECTION 15.4

Regulating Metabolism of Many Cells: G Protein–Coupled Receptors That Activate or Inhibit Adenylyl Cyclase

- Ligand binding by G protein–coupled receptors that activate $G_{\alpha s}$ results in the activation of the membrane-bound enzyme adenylyl cyclase, which converts ATP to the second messenger cAMP. Ligand binding of G protein–coupled receptors that activate $G_{\alpha i}$ results in the inhibition of adenylyl cyclase and lower levels of cAMP.
- $G_{\alpha s}\cdot GTP$ and $G_{\alpha i}\cdot GTP$ bind to the catalytic domain in adenylyl cyclase to activate or inhibit the enzyme, respectively.
- cAMP binds cooperatively to a regulatory subunit of PKA, releasing the active kinase catalytic subunit.
- In liver and muscle cells, activation of PKA induced by epinephrine and other hormones exerts a dual effect, inhibiting glycogen synthesis and stimulating glycogen breakdown via a kinase cascade. The result is an increase in glucose for production of ATP.
- PKA mediates the diverse effects of cAMP in most cells. The substrates for PKA, and thus the cellular responses to hormone-induced activation of PKA, vary among cell types.
- The signal that activates the GPCR/adenylyl cyclase/cAMP/PKA signaling pathway is amplified tremendously by second messengers and kinase cascades.
- Activation of PKA often leads to phosphorylation of nuclear CREB protein, which, together with the CBP/P300 co-activator, stimulates transcription of genes, thus initiating a long-term change in the cell's protein composition.
- Localization of PKA to specific regions of the cell by anchoring proteins restricts the effects of cAMP to particular locations in the cell.
- Signaling from G_s-coupled receptors is down-regulated by multiple mechanisms: first, the intrinsic GTPase activity of $G_{\alpha s}$ that converts the bound GTP to GDP is enhanced when $G_{\alpha s}$ binds to adenylyl cyclase (this occurs when many $G_{\alpha}\cdot GTP$ complexes bind to their respective effector proteins); and second, PDE acts to hydrolyze cAMP to $5'\text{-AMP}$, terminating the cellular response.
- Most GPCRs are regulated by *feedback repression*. They are deactivated by kinases in the G-protein–receptor kinase (GRK) family, which phosphorylate cytosolic residues of the receptor in its active R^* conformation. GRK phosphorylation of ligand-bound β-adrenergic receptors also leads to the binding of arrestin and endocytosis of the

receptors. The consequent reduction in the number of cell-surface receptors renders the cell less sensitive to additional hormone.

- The GPCR-arrestin complex functions as a scaffold that activates several cytosolic kinases, initiating cascades that lead to transcriptional activation of many genes controlling cell growth.

15.5 Regulating Protein Secretion and Muscle Contraction: Ca^{2+} Ions as Second Messengers in Multiple Signal Transduction Pathways

A small rise in cytosolic Ca^{2+} induces a variety of cellular responses, depending on cell type: endocrine cells secrete hormones, pancreatic acinar cells secrete digestive enzymes, neurons release neurotransmitter at the synapse, and muscle fibers contract (Table 15-4). For example, in response to acetylcholine stimulation of GPCRs, secretory cells of the pancreas and of the parotid (salivary) glands secrete digestive proteins. In this case, a rise in cytosolic Ca^{2+} triggers the fusion of secretory vesicles with the plasma membrane and release of their protein contents into the extracellular space. Thrombin, a proteolytic enzyme in the blood-clotting cascade, binds to a GPCR on blood platelets. The binding of thrombin (which activates the GPCR by proteolytic cleavage of the receptor extracellular domain) triggers a rise in cytosolic Ca^{2+}, which in turn causes a shape change in the platelets and other modifications that lead to their aggregation, an important step in blood clotting to prevent blood from leaking out of damaged blood vessels. Thrombin inhibitors are drugs that block blood coagulation.

TABLE 15-4 • Cellular Responses to Hormone-Induced Rise in Cytosolic Ca^{2+} in Various Tissues[iii]

Tissue	Hormone Inducing Rise in Ca^{2+}	Cellular Response
Pancreas (acinar cells)	Acetylcholine	Secretion of digestive enzymes, such as amylase and trypsinogen
Parotid (salivary) gland	Acetylcholine	Secretion of amylase
Vascular or stomach smooth muscle	Acetylcholine	Contraction
Liver	Vasopressin	Conversion of glycogen to glucose
Blood platelets	Thrombin	Aggregation, shape change, secretion of hormones
Mast cells	Antigen	Histamine secretion
Fibroblasts	Peptide growth factors	DNA synthesis, cell division (e.g., bombesin and PDGF)
Nerve cells	Many	Secretion of neurotransmitters

[iii]Hormone stimulation leads to production of inositol 1,4,5-trisphosphate (IP_3), a second messenger that promotes release of Ca^{2+} stored in the endoplasmic reticulum.
SOURCE: M. J. Berridge, 1987, *Annu. Rev. Biochem.* **56**:159; and M. J. Berridge and R. F. Irvine, 1984, *Nature* **312**:315.

The total calcium present in a subcellular compartment is the sum of the free Ca^{2+} ions and bound Ca^{2+}. Free Ca^{2+} ions are Ca^{2+} ions that are not tightly bound to proteins and that can be quantified by the fluorescence techniques mentioned previously. In the ER and mitochondrial matrix space, the amounts of bound Ca^{2+} are thought

to be much greater than those of free Ca^{2+} because these organelles contain abundant Ca^{2+}-binding proteins. As an example, the ER lumen contains several Ca^{2+}-binding proteins, including the chaperones *calreticulin* and *calnexin* (Chapter 13), which have a low affinity and large capacity for Ca^{2+} binding and that buffer the amount of calcium in the lumen of that organelle, ${Ca^{2+}}_{ER}$. Measurements of free $[Ca^{2+}]$ have indicated that, while the concentrations can vary considerably among different types of resting cells, typically $[{Ca^{2+}}_{cytosol}] = \sim 100\ nM$, $[{Ca^{2+}}_{ER}] = \sim 400\ \mu M$, and $[{Ca^{2+}}_{mitochondria}] = \sim 100\ nM$.

The free Ca^{2+} concentration in organelles can vary in response to stimulation by hormones or neuronal signals, but $[{Ca^{2+}}_{cytosol}]$ often increases to about $1\ \mu M$ and $[{Ca^{2+}}_{mitochondria}]$ to approximately $1 - 10\ \mu M$, whereas $[{Ca^{2+}}_{ER}]$ decreases to about $100\ \mu M$. We learned in Chapter 12 that increases in the concentration of free Ca^{2+} in the mitochondrial matrix accelerate pyruvate oxidation and ATP production. Thus, in muscle, increases in the concentration of Ca^{2+} are used both to induce contractions and to increase mitochondrial ATP synthesis to provide the energy to fuel those contractions.

Products of the Hydrolysis of the Membrane Lipid Phosphatidylinositol

4,5-Bisphosphate by Phospholipase C Elevate Cytosolic Ca^{2+} Levels

A number of important second messengers, used in several signal transduction pathways, are derived from the membrane lipid *phosphatidylinositol* (*PI*; Figure 15-27). One of these, IP_3, triggers the elevation of Ca^{2+} in the cytosol and mitochondrial matrix. IP_3 is generated in several steps from the precursor PI.

FIGURE 15-27 Synthesis of second messengers DAG and IP_3 from phosphatidylinositol (PI). Each membrane-bound PI kinase places a phosphate (yellow circles) on a specific hydroxyl group on the inositol ring, producing the phosphorylated derivatives PI(4)P and $PI(4,5)P_2$. Cleavage of $PI(4,5)P_2$ by phospholipase C yields the two important second messengers DAG and IP_3. Signaling is terminated when a phosphatase removes the 5-phosphate from IP_3; a second phosphatase removes the 1-phosphate, and the inositol 4-

phosphate is reused to synthesize PI 4-phosphate. See A. Toker and L. C. Cantley, 1997, *Nature* **387**:673; and C. L. Carpenter and L. C. Cantley, 1996, *Curr. Opin. Cell Biol.* **8**:153.

In the plasma membrane this phospholipid resides in the cytoplasmic leaflet with its inositol head group always facing the cytosol. Inositol can be phosphorylated on one or more hydroxyl groups by the combined actions of different kinases, and the phosphates can be removed by phosphatases, as discussed in Chapter 16. One derivative of PI, the lipid phosphatidylinositol 4,5-bis phosphate [$PI(4,5)P_2$], is made by stepwise addition of two phosphates to PI to the hydroxyl groups attached to the #4 and #5 carbon atoms of the inositol ring.

When the enzyme *phospholipase C (PLC)* is activated by a signal transduction pathway, it catalyzes the cleavage of $PI(4,5)P_2$ in the plasma membrane into two important second messengers: 1,2-diacylglycerol (DAG), a lipophilic molecule that remains associated with the plasma membrane, and inositol 1,4,5-trisphosphate (IP_3), which can freely diffuse in the cytosol (see Figures 15-27 and 15-28). We refer to downstream events involving these two second messengers collectively as the *IP_3/DAG pathway*. IP_3, in turn, triggers the release of Ca^{2+} from the ER into the cytosol and mitochondrial matrix.

FIGURE 15-28 The IP_3/DAG pathway and the elevation of cytosolic Ca^{2+}. Opening of endoplasmic reticulum Ca^{2+} channels can be triggered by ligand binding to GPCRs that primarily activate members of the G_q family, leading to activation of phospholipase C (step **1**). Cleavage of $PI(4,5)P_2$ by phospholipase C yields IP_3 and DAG (step **2**). After diffusing through the cytosol, IP_3 interacts with and opens IP_3-gated Ca^{2+} channels, often termed *IP_3 receptors* or *IP_3R's* in the membrane of the endoplasmic reticulum (step **3**), causing release of Ca^{2+} ions stored in the ER lumen into the cytosol (step **4**). One of several cellular responses induced by a rise in cytosolic Ca^{2+} is recruitment of protein kinase C (PKC) to the plasma membrane (step **5**), where it is activated by binding DAG (step **6**). The activated membrane-associated kinase can phosphorylate various cellular enzymes and receptors, thereby altering their activity (step **7**). See J. W. Putney, 1999, *Proc. Nat'l. Acad. Sci. USA* **96**:14669; Y. Zhou, 2010, *Proc. Nat'l. Acad. Sci. USA* **107**:4896; M. Cahalan, 2010, *Science* **330**:43; and Q. C. Wang, X. Wang, and T.-S. Tang, 2018, *J. Cell Biol.* **217**(6):1899–1900, https://doi.org/10.1083/jcb.201805037.

Phospholipase C is activated by binding either ${}^{GTP}G_{\alpha o}$ or ${}^{GTP}G_{\alpha q}$ subunits released after GPCR activation (Figure 15-28, step **1**). In turn, activated phospholipase C cleaves $PI(4,5)P_2$ into DAG and IP_3 (see Figure 15-28, step **2**). The two second messengers trigger

distinct, but sometimes interrelated, downstream pathways. Some phospholipase C's are activated by receptors other than GPCRs and are described in the following chapter.

Ca^{2+} Release from the ER Triggered by IP_3

Ligand binding to G protein–coupled receptors that activate phospholipase C induces an elevation in cytosolic Ca^{2+} even when Ca^{2+} ions are absent from the surrounding extracellular fluid. In this case, Ca^{2+} is released into the cytosol from the ER lumen (where, as noted above, Ca^{2+} can accumulate to almost millimolar concentrations by binding to Ca^{2+}-binding proteins) through the operation of *IP_3-gated Ca^{2+} channels* in the ER membrane, as depicted in Figure 15-28 (steps **3** and **4**). Each of these large IP_3-gated channels is composed of four identical subunits, and each subunit contains an IP_3-binding site in its N-terminal cytosol-facing domain. IP_3 binding induces opening of the channel, allowing Ca^{2+} to flow down its concentration gradient from the ER lumen into the cytosol. This family of IP_3-gated Ca^{2+} channel proteins is similar in structure to the family of voltage-sensitive Ca^{2+} channels that are called *ryanodine receptors* and that reside in a specialized ER in muscle cells called the *sarcoplasmic reticulum* (see Chapter 17).

The rise in the cytosolic Ca^{2+} level is transient because Ca^{2+} pumps located in the plasma membrane and in the ER membrane actively transport Ca^{2+} from the cytosol to the cell exterior or back into the ER lumen, respectively. Furthermore, within a second of its generation, the phosphate linked to carbon 5 of IP_3 is hydrolyzed, yielding inositol 1,4-bisphosphate (IP_2) (see Figure 15-27). IP_2 cannot open IP_3-gated Ca^{2+} channels.

Once released, the Ca^{2+} ions trigger further steps leading to the cellular response. As detailed in Chapter 3, the ubiquitous small cytosolic protein calmodulin functions as a multipurpose switch protein that mediates many cellular effects of Ca^{2+} ions. Binding of Ca^{2+} to four sites on calmodulin triggers a major conformational change that allows calmodulin to bind to and modulate the activity of many enzymes and other proteins (see Figure 3-34). Because four Ca^{2+} ions bind to calmodulin in a cooperative fashion, a small change in the level of cytosolic Ca^{2+} leads to a large change in the level of active calmodulin. One well-studied enzyme activated by the Ca^{2+}-calmodulin complex is myosin light-chain kinase, which regulates the activity of myosin and thus contraction in smooth muscle cells (see Chapter 17). Another is cAMP phosphodiesterase (PDE), the enzyme that degrades cAMP to 5′-AMP and terminates its effects (see Figure 15-18). This reaction thus links Ca^{2+} and cAMP, one of many examples in which two second messenger–mediated pathways interact to fine-tune a cellular response.

IP_3-triggered Ca^{2+} Transport from the ER to the Mitochondrial Matrix

In some cells, a cellular response to IP_3 takes place in the mitochondrial matrix in addition to the cytosol. In Chapter 12, we learned that there are direct contacts between specialized regions of the ER membrane, called *mitochondria-associated membranes (MAMs)*, and the outer mitochondrial membrane. These contacts affect mitochondrial structure, dynamics, and function. In response to elevated IP_3, Ca^{2+} is able to move from the ER lumen through the MAMs into the mitochondrial matrix (Figure 15-29). Once in the matrix, the elevated Ca^{2+} levels increase ATP synthesis as well as enhance mitochondrial activity in other ways.

FIGURE 15-29 Movement of Ca^{2+} between the cytosol, mitochondrion, and endoplasmic reticulum. The ER is the main intracellular storage depot for Ca^{2+}. Binding of IP_3 to IP_3-gated Ca^{2+} channels (IP_3R) in the membrane of the endoplasmic reticulum releases Ca^{2+} into the cytosol (step **1a**); the IP_3-gated Ca^{2+} channels in the mitochondria-associated membranes (MAMs) of the ER are also opened by binding of IP_3 (step **1b**). Step **2**: VDAC channels in the outer mitochondrial membrane segments adjacent to MAMs are physically linked to IP_3Rs by the GRP75 protein; they directly and efficiently pass the Ca^{2+} released from the MAMs into the mitochondrial intermembrane space. Step **3**: The high concentration of Ca^{2+} in the intermembrane space induces the opening of MCU Ca^{2+} channels and other Ca^{2+} channels in the inner membrane, resulting in the flow of Ca^{2+} into the mitochondrial matrix. Step **4**: Over time, Ca^{2+} is released from the mitochondrial matrix into the intermembrane space by Ca^{2+}/Na^+ and Ca^{2+}/H^+ antiporters in the inner membrane, then transferred into the cytosol through VDAC or other Ca^{2+} channels in the outer membrane. Finally, pumping of Ca^{2+} from the cytosol by ATP-powered Ca^{2+} pumps in the ER membrane (step **5**) or plasma membrane restores the high ER Ca^{2+} and low cytosolic Ca^{2+} levels. See M. Schäfer et al., 2014, *Cell Tissue Res.* **357**:395; and K. Kamer and V. Mootha, 2015, *Nat. Rev. Mol. Cell Biol.* **16**:545.

The Ca^{2+} has to cross three separate membranes to reach the mitochondrial matrix. As detailed above, IP_3-gated Ca^{2+} channels in the ER membrane (step **1a**), including those in the MAMs (step **1b**), open in response to a rise in cytosolic IP_3. Voltage-dependent anion channels (VDACs) in the outer mitochondrial membrane adjacent to the MAMs, and which are physically linked by the GRP75 protein to these IP_3-gated Ca^{2+} channels, efficiently pass the Ca^{2+} released from the ER lumen into the intermembrane space (step **2**). A mitochondrial calcium uniporter (MCU) in the inner

mitochondrial membrane then transports Ca^{2+} from the intermembrane space into the mitochondrial matrix (step **3**).

MCUs open only in the presence of a high Ca^{2+} concentration in the intermembrane space. Regulatory subunits of the MCU that face the intermembrane space have Ca^{2+}-binding EF hands (see Chapter 3) with relatively low binding affinity for Ca^{2+}; these subunits must bind calcium for the MCU to open. Individuals with mutations in the gene encoding one of these subunits have skeletal muscle defects and learning disabilities, symptoms that can accompany other mitochondrial disorders. The consequences of these mutations attest to the importance of these uniporters in mitochondrial metabolism.

Too much calcium in the mitochondrial matrix is potentially toxic. To avoid the buildup of excess calcium, the mitochondrial matrix gradually releases Ca^{2+} into the cytosol. The calcium first moves across the inner mitochondrial membrane into the intermembrane space via Na^+/Ca^{2+} and H^+/Ca^{2+} antiporters, then crosses the outer mitochondrial membrane into the cytosol, most likely via VDACs (step **4**). The calcium transport cycle is completed when cytosolic calcium enters the ER via an ATP-powered Ca^{2+} pump (step **5**; see Figure 11-10) or is pumped out of the cell by ATP-powered Ca^{2+} pumps in the plasma membrane.

The Store-Operated Ca^{2+} Channel in the Plasma Membrane

If the IP_3-gated Ca^{2+} channel in the ER membrane stays open long enough, coupled with operation of the plasma-membrane Ca^{2+} export pump, the outflow of Ca^{2+} would eventually deplete the stores of Ca^{2+} in both the ER and mitochondrial matrix, and a cell would soon be unable to increase the cytosolic Ca^{2+} level in response to hormone-induced generation of IP_3. Using patch-clamping studies (see Figure 11-22), investigators established that cells must have a Ca^{2+} channel in the plasma membrane, called the *store-operated channel (SOC)*, that opens and admits extracellular Ca^{2+} into the cytosol when Ca^{2+} stores in the ER are depleted. The SOC thereby provides Ca^{2+} to replenish the ER and mitochondrial stores. To function, a SOC would require some additional ER-associated protein that could sense Ca^{2+} depletion in the ER and signal the SOC to open.

Initial attempts to identify a SOC were not successful because investigators focused on potential Ca^{2+} channel proteins with typical channel sequences and structures. Eventually investigators established the identity of this channel protein as *Orai1*; the sequence and three-dimensional structure of Orai1 is unlike that of any other known ion-channel protein.

The protein that senses Ca^{2+} depletion in the ER is called *STIM1*. It is a transmembrane protein in the ER membrane (Figure 15-30a) that binds Ca^{2+} when its concentration in the lumen of the ER is high. To bind Ca^{2+}, STIM1 uses an EF hand motif, similar to that in calmodulin (see Figure 3-34), located on the luminal side of the ER membrane. STIM1 is also bound to several cytosolic proteins and, via the EB1 protein, to cytosolic microtubules, all of which keep STIM1 away from the plasma membrane. As stores of Ca^{2+} in the ER are depleted, the STIM proteins lose their bound Ca^{2+}, oligomerize, and dissociate from EB1 and other cytosolic proteins. No longer anchored by these proteins, STIM proteins diffuse in the ER membrane to segments closely juxtaposed to the plasma membrane (Figure 15-30b). There portions of the STIM, called *CAD domains*, bind to and trigger the opening of Orai1, allowing the influx of extracellular Ca^{2+}; these two proteins are the key components of the store-operated Ca^{2+} pathway. Once the level of cytosolic Ca^{2+} rises to normal, a complex of Ca^{2+} bound to the protein calmodulin (Chapter 3) binds to Orai1, preventing STIM1 from binding to the ion channel and shutting down Ca^{2+} entry.

FIGURE 15-30 Opening of store-operated Ca^{2+} channels in the plasma membrane. (a) In the resting cell, Ca^{2+} levels in the ER lumen are high. Ca^{2+} ions (blue circles) bind to the luminal EF hand domains of the transmembrane STIM1 proteins, which are distributed throughout the ER. STIM1 binds to EB1, a protein that also binds to the $(+)$ ends of cytosolic microtubules. Binding to EB1 traps STIM1 molecules from translocating to sites where the ER and plasma membrane are juxtaposed. (b) As Ca^{2+} stores in the ER are depleted, Ca^{2+}

ions dissociate from the EF hands. STIMs undergo oligomerization, weakening their binding to EB1, and relocate to areas of the ER membrane near the plasma membrane. There the STIM CAD domains (orange) bind to and trigger the opening of the store-operated Ca^{2+} channels (Orai1) in the plasma membrane, allowing influx (black arrow) of extracellular Ca^{2+} into the cytosol.

Feedback Loops in ER and Cytosol Cycling of Ca^{2+} Trigger Oscillations in the Cytosolic Ca^{2+} Concentration

In the case of certain G protein–coupled receptors, their continuous activation induces rapid, repeated spikes in the level of cytosolic Ca^{2+} (Figure 15-31) rather than a prolonged elevation in cytosolic Ca^{2+}. These oscillations are caused by complex feedback interactions between the cytosolic Ca^{2+} concentration and the IP_3-gated Ca^{2+} channels in the ER membrane. In unstimulated, resting cells, activation of a GPCR triggers a rise in IP_3, and the rise in IP_3 in turn leads to a rapid rise in cytosolic Ca^{2+}. However, the high cytosolic Ca^{2+} level reached at the peak of the spike inhibits the further release of Ca^{2+} from ER stores by binding to the IP_3-gated Ca^{2+} channels and decreasing their affinity for IP_3. As a result, these Ca^{2+} channels close, and the cytosolic Ca^{2+} level drops rapidly as Ca^{2+} is pumped back into the ER lumen or out of the cell. Thus cytosolic Ca^{2+} is a feedback inhibitor of the IP_3-gated Ca^{2+} channels that, when open, trigger a rise in cytosolic Ca^{2+}.

FIGURE 15-31 Oscillations in the cytosolic Ca^{2+} concentration following treatment of human HeLa cells with histamine. Like the LH receptors described in the text, the histamine GPCR activates the IP_3-DAG signaling pathway. The feedback loops generating the spikes in the cytosolic Ca^{2+} concentration are detailed in the text.

[Data from A. Miyawaki et al., 1997, *Nature* **388**:882.]

As an example, this mechanism produces calcium ion oscillations in the pituitary gland cells that secrete luteinizing hormone (LH), which plays an important role in controlling ovulation and thus female fertility. LH secretion is induced by the binding of luteinizing hormone–releasing hormone (LHRH) to its G protein–coupled receptors on the surfaces of these cells; LHRH binding induces repeated Ca^{2+} spikes. Each Ca^{2+} spike induces exocytosis of a few

LH-containing secretory vesicles, presumably those close to the plasma membrane, increasing the level of LH in the circulation.

DAG Activates Protein Kinase C

Recall that the hydrolysis of $PI(4,5)P_2$ by phospholipase C produces two products, IP_3 and DAG. DAG is also a second messenger, and its principal function is to activate a family of protein kinases collectively termed *protein kinase C (PKC)*.

After its formation, the hydrophobic DAG (see Figure 15-28) remains associated with the inner leaflet of the plasma membrane. In the absence of hormone stimulation, its target protein kinase C is present in the cytosol as a soluble protein that is catalytically inactive. A rise in the cytosolic Ca^{2+} level causes protein kinase C to translocate to the cytosolic surface of the plasma membrane, where it can bind to and become activated by phosphatidylserine and DAG (see Figure 15-28, steps **5** and **6**). Activation of PKC thus depends on an increase of both Ca^{2+} ions and DAG, suggesting an interaction between the two branches of the IP_3/DAG pathway.

The activation of PKC in different cells results in a varied array of cellular responses, indicating that it plays a key role in many aspects of cellular growth and metabolism. In many cells, PKC phosphorylates transcription factors that are localized in the

cytosol, triggering their movement into the nucleus, where they activate genes necessary for cell division. In liver cells, PKC helps regulate glycogen metabolism by phosphorylating and so inhibiting glycogen synthase.

Integration of Ca^{2+} and cAMP Second Messengers Regulates Glycogenolysis

All cells constantly receive multiple signals from their environment, including changes in levels of hormones and metabolites, and all of these signals must be integrated. The breakdown of glycogen to glucose (glycogenolysis) provides an excellent example of how cells can integrate their responses to more than one signal. As discussed in Section 15.4, stimulation of muscle and liver cells by epinephrine leads to a rise in the second messenger cAMP, which promotes glycogen breakdown (see Figure 15-22a). In both muscle and liver cells, other signaling pathways produce the same cellular response of enhanced glycogenolysis.

In striated muscle cells (see Figure 17-29), stimulation by nerve impulses causes the release of Ca^{2+} ions from the sarcoplasmic reticulum and an increase in the cytosolic Ca^{2+} concentration, which triggers muscle contraction. With the rise in cytosolic Ca^{2+}, Ca^{2+} also binds to the calmodulin subunit of glycogen phosphorylase kinase (GPK), thus partially stimulating its kinase

catalytic activity. GPK then phosphorylates and thus activates its target glycogen phosphorylase. That enzyme stimulates the degradation of glycogen to glucose-1-phosphate, which provides fuel for prolonged muscle contraction.

As blood epinephrine concentrations rise, adenylyl cyclase is activated and cAMP concentrations increase, activating PKA. Recall that phosphorylation by PKA also activates GPK (see Figure 15-22). We see that maximal activation of GPK, and therefore a maximal rate of glycogenolysis, requires both phosphorylation and Ca^{2+}. Thus, in muscle, a key regulator of glycogenolysis, *GPK*, is subject to regulation by both nerve signals and hormones and integrates both signal transduction pathways (Figure 15-32).

FIGURE 15-32 Integrated regulation of glycogenolysis by Ca^{2+} and cAMP/PKA pathways. Neuronal stimulation of striated muscle cells or the binding of epinephrine to β-adrenergic receptors on their surfaces leads to an increase in the cytosolic concentrations of the second messengers Ca^{2+} and cAMP, respectively. The key regulatory enzyme glycogen phosphorylase kinase (GPK) is activated both by binding Ca^{2+} ions and by phosphorylation by cAMP-dependent PKA. Enzymes are marked by white boxes.
$(+)=$ activation of enzyme activity; $(-)=$ inhibition.

KEY CONCEPTS OF SECTION 15.5

Regulating Protein Secretion and Muscle Contraction: Ca^{2+} Ions as Second Messengers in Multiple Signal Transduction

Pathways

- A small rise in cytosolic Ca^{2+} induces a variety of responses in different cells, including hormone secretion, contraction of muscle, and platelet aggregation.
- Many hormones bind GPCRs coupled to G proteins containing a $G_{\alpha q}$ subunit. The effector protein activated by GTP-bound $G_{\alpha q}$ is a phospholipase C enzyme.
- Phospholipase C cleaves a phospholipid in the cytosolic leaflet of the plasma membrane known as $PI(4,5)P_2$, generating two second messengers: water-soluble IP_3 and membrane-bound DAG.
- IP_3 triggers the opening of IP_3-gated Ca^{2+} channels in the endoplasmic reticulum and elevation of cytosolic free Ca^{2+}.
- Opening of IP_3-gated Ca^{2+} channels in the endoplasmic reticulum also leads to an increase in Ca^{2+} in the mitochondrial matrix and an acceleration of ATP synthesis.
- Depletion of ER Ca^{2+} stores leads to the opening of plasma-membrane store-operated Ca^{2+} channels and an influx of Ca^{2+} from the extracellular medium.
- In response to elevated cytosolic Ca^{2+}, protein kinase C is recruited to the plasma membrane, where it is activated by DAG.
- Glycogen breakdown and synthesis in muscle is coordinately regulated by the second messengers Ca^{2+} and cAMP, whose levels are regulated by neural and hormonal stimulation, respectively.

15.6 Vision: How the Eye Senses Light

Animals have a remarkable ability to perceive the world thanks to their ability to sense and respond to physical stimuli. One of the most important of these stimuli is light. To understand light-initiated signal transduction, we will focus on one of the two types of photoreceptor cells in the human retina, the *rods* (Figure 15-33).

FIGURE 15-33 Human rod cell. (a) Schematic diagram of an entire rod cell. At the synaptic terminal (also called the *spherule*), the rod cell forms synapses with one or more interneurons. Rhodopsin, a light-sensitive G protein–coupled receptor, is located in the flattened membrane disks of the cell's outer segment. (b) Electron micrograph of the region of the rod cell indicated by the bracket in (a). This region includes the junction of the inner and outer segments. (c) Structure of the human retina, illustrating the layer of pigment epithelial cells that underlie the rods and cones and in which all-*trans*-retinol is converted to 11-*cis*-retinal before being shuttled back to the rod and cone cells.

[Part (b) Don W. Fawcett/Science Source. Part (c) after drawing by Alapakkam P. Sampath.]

Light Activates Rhodopsin in Rod Cells of the Eye

Rod cells are stimulated by weak light such as moonlight and are almost entirely responsible for night vision; they have little role in

color vision. The other type of human photoreceptor cells, *cones*, are involved in color vision and use a similar signal transduction pathway. These photoreceptor cells signal to (synapse with) layer upon layer of interneurons at the back of the eye that are innervated by different combinations of photoreceptor cells. All these signals are processed and relayed through the visual thalamus to the part of the brain called the *visual cortex*, where they are interpreted.

Rod cells sense light with the aid of a light-sensitive GPCR called *rhodopsin*. Rhodopsin has two components: the protein opsin, a typical member of the GPCR A family with seven transmembrane α-helical segments, and a light-absorbing pigment called 11-*cis*-retinal that is covalently bound to opsin (Figure 15-34a). The bound 11-*cis*-retinal locks the rhodopsin into its inactive (R) conformation, preventing any signaling in the absence of light. Rhodopsin, found only in rod cells (cone cells have homologous photoreceptor molecules), is localized to the thousand or so flattened membrane disks that make up the outer segment of each of these rod-shaped cells (see Figure 15-33). There are about 90 million rod cells in the human retina, and each contains about 4×10^7 molecules of rhodopsin that are very densely packed in the membrane disks. The heterotrimeric G protein coupled to rhodopsin, called *transducin* (G_t), contains a G_α subunit referred to as $G_{\alpha t}$; like rhodopsin, $G_{\alpha t}$ is found only in rod cells.

FIGURE 15-34 Vision depends on the light-triggered isomerization of the retinal moiety of rhodopsin. (a) Rhodopsin consists of the light-absorbing pigment 11-*cis*-retinal covalently attached to the amino group of lysine residue 296 in the opsin protein. (b) Absorption of light causes rapid photoisomerization of the bound *cis*-retinal to the all-*trans* isomer, triggering a conformational change in opsin that enables it to activate the G protein transducin.

Rhodopsin differs from other GPCRs in that binding of a ligand does not activate the receptor. Rather, the activating signal is the absorption of a photon of light by the bound retinal (Figure 15-34b). On absorption of a photon, the retinal moiety of rhodopsin is rapidly converted from the *cis* isomeric form (11-*cis*-retinal) to the all-*trans* isomeric form. This change of shape of the retinal induces a change in the protein from its inactive (R) to active (R*) conformation, equivalent to the activating conformational change that occurs upon ligand binding to other GPCRs. As a consequence, the R* form of

rhodopsin binds to transducin, triggering exchange of GTP for GDP on its $G_{\alpha t}$ subunit. At the same time, transducin also dissociates into its $G_{\alpha t}$·GTP and $G_{\beta\gamma}$ subunits. A single activated rhodopsin protein activates ~13 transducin molecules in the few seconds before the covalent bond between the opsin protein and all-*trans*-retinal is spontaneously cleaved; once the all-*trans*-retinal has dissociated opsin can no longer activate transducin.

The free all-*trans*-retinal is converted back to 11-*cis*-retinal in multiple steps. First, all-*trans*-retinal is converted to an intermediate, all-*trans*-retin*ol*, by an enzyme in the outer segment of the rod. This intermediate is then shuttled by a series of transport proteins to the adjacent *pigment epithelial cells* in the retina (Figure 15-33c), where it is converted to 11-*cis*-retinal. The 11-*cis*-retinal is then shuttled back to the rod cells where it binds to opsin, forming rhodopsin and completing the rhodopsin visual cycle.

RPE65 is the enzyme in the pigment epithelial cells of the retina that catalyzes the isomerization of the intermediate esterified all-*trans*-retinol to 11-*cis*-retinol. Autosomal recessive mutations in the RPE65 gene are a frequent cause of blindness in children. In 2017, the U.S. Food and Drug Administration approved the first in vivo human gene therapy in the United States, one to treat blindness based on a defective RPE65 enzyme. In this treatment, an adeno-associated virus vector injected directly into the retina is used to introduce a complete copy of the *RPE65* gene into the pigment

epithelial cells. All young recipients reported an increase in visual acuity and improved ability to negotiate mazes. ■

Activation of Rhodopsin by Light Leads to Closing of cGMP-Gated Cation Channels

In the dark, the potential across the plasma membrane of a rod cell is about $-30\ \mathrm{mV}$. That is considerably more positive (less negative) than the resting potential (-60 to $-90\ \mathrm{mV}$) typical of neurons and other electrically active cells (see Chapter 11). This state of the membrane, called the **depolarized state**, causes rod cells in the dark to release neurotransmitters constantly. Thus the neurons with which they synapse are constantly being stimulated; the signal they send to the brain through a series of neurons is perceived as darkness. The plasma membrane of a resting rod cell remains in this depolarized state because a large number of open ion channels admit both Na^+ and Ca^{2+} into the cell (hence they are called *nonselective*). Recall from Chapter 11 that movement of cations (positively charged ions) such as Na^+ and Ca^{2+} from the outside of the cell to the inside will reduce the magnitude of the inside-negative membrane potential, or depolarize the membrane.

These nonselective cation channels open in response to (are "gated" by) binding of the second messenger **cyclic guanosine**

monophosphate, or **cGMP** (see Figure 15-5). The outer segments of resting rod cells contain an unusually high concentration ($\sim$0.07 mM) of cGMP, which is generated from GTP in a reaction catalyzed by guanylyl cyclase. Thus in the dark the high cGMP concentration holds many of the cGMP-gated channels in the open state, depolarizing the membrane.

Light acts by lowering the concentration of cGMP and thereby closing these nonselective cation channels (Figure 15-35). Absorption of light by rhodopsin leads to receptor and then G_t activation. Almost instantaneously, $G_{\alpha t}$·GTP triggers the activation of *cGMP phosphodiesterase (PDE)*, which hydrolyzes cGMP to 5′-GMP. As the cGMP concentration drops, the nonselective cation channels close and the membrane potential becomes *more* negative inside (see Figure 15-35, step **6**). This repolarization of the plasma membrane, in turn, causes a reduction in neurotransmitter release. The more photons are absorbed by rhodopsin, the more cGMP is hydrolyzed, and the more channels are closed. The fewer Na^+ and Ca^{2+} ions cross the membrane from the outside, the more inside negative the membrane potential becomes, and so the less neurotransmitter is released. The reduction in neurotransmitter release is transmitted to the brain by a series of neurons, where it is perceived as light.

FIGURE 15-35 The light-activated rhodopsin pathway and the closing of cation channels in rod cells. In dark-adapted rod cells, a high level of cGMP keeps cGMP-gated plasma membrane nonselective cation channels open, leading to influx of Na^+ and Ca^{2+}, depolarization of the plasma membrane, and neurotransmitter release. Light absorption generates activated rhodopsin, R^* (step 1), which binds inactive, GDP-bound $G_{\alpha t}$ protein and mediates the exchange of GDP for GTP (step 2). The free $G_{\alpha t}{\cdot}GTP$ generated then activates PDE by binding to its inhibitory γ subunits (step 3) thus dissociating them from the catalytic α and β subunits (step 4). Relieved of their inhibition, the α and β subunits of PDE hydrolyze cGMP to GMP (step 5). The resulting decrease in cytosolic cGMP leads cGMP to dissociate from the cation channels in the plasma membrane and causes these channels to close (step 6). As a result the plasma membrane then becomes transiently hyperpolarized, and neurotransmitter release is reduced. The complex of $G_{\alpha t}{\cdot}GTP$ and the PDE γ subunits binds a GTPase-activating complex formed of the components RGS9 and Gβ5 (step 7); by hydrolyzing the bound GTP, this complex triggers the physiologically important rapid inactivation of the PDE (step 8). See V. Arshavsky and E. Pugh, 1998, *Neuron* **20**:11; and V. Arshavsky, 2002, *Trends Neurosci.* **25**:124.

As depicted in Figure 15-35, lipid anchors confine both $G_{\alpha t}$·GTP and its effector, PDE, to the cytosolic face of the disk membranes of the rod cell. The $G_{\alpha t}$·GTP complexes that are generated through activation of rhodopsin are able to move laterally along the membrane surface and bind to the two inhibitory γ subunits of PDE (see Figure 15-35); note that the stoichiometry is 1:1, that is, one $G_{\alpha t}$·GTPbinds to one γ subunit. The binding of $G_{\alpha t}$·GTP to the γ subunits releases the catalytically active αβ dimer, which then converts cGMP to GMP. This is another example of how removal of an inhibitory subunit can quickly activate an enzyme, a common mechanism in signaling pathways.

Direct support for the role of cGMP in rod-cell activity has been obtained in patch-clamping studies using isolated patches of plasma membrane taken from the rod outer segment, which contains abundant cGMP-gated cation channels. When cGMP is added to the cytosolic surface of these patches, the number of open cation channels increases rapidly; cGMP binds directly to a site on the cytosolic surface of the channel proteins to keep them open. Like the K^+ channels discussed in Chapter 11, the cGMP-gated channel protein contains four subunits. In this case, each of the subunits is able to bind a cGMP molecule. Three or four cGMP molecules must bind to each channel in order to open it; because of this cooperative allosteric interaction, channel opening is very sensitive to small changes in cGMP levels.

Signal Amplification Makes the Rhodopsin Signal Transduction Pathway Exquisitely Sensitive

Remarkably, a single photon absorbed by a resting rod cell produces a measurable response in the form of a small hyperpolarization in the membrane potential of about 1 mV, which in amphibians lasts a second or two. With their 90 million rod cells, dark-adapted human eyes are able to perceive as light the absorption of as few as five photons; the ability to respond to a very few photons is critical to night vision.

The light-detecting system is very sensitive because the signal is greatly amplified by the signal transduction pathway. During the time it is active, each rhodopsin molecule in the disk membrane of a rod cell can activate $\sim$13 $G_{\alpha t}$ molecules, two of which in turn activate a single phosphodiesterase molecule (see Figure 15-35). Each PDE molecule hydrolyzes hundreds of cGMP molecules during the fraction of a second it remains active. The absorption of a single photon — yielding a single activated rhodopsin molecule — can reduce the cGMP concentration enough to trigger the closing of thousands of cation channels (or about 5 percent of the open channels) in the plasma membrane, causing a measurable change in the membrane potential of the cell.

Rapid Termination of the Rhodopsin Signal Transduction Pathway Is Essential for the Temporal Resolution of Vision

In many organisms a fast response to rapidly changing light conditions (dark-to-light and light-to-dark) is critical for survival. As in all GPCR-mediated signaling pathways, after a light-to-dark transition all the activated intermediates must be inactivated rapidly to shut down the signaling pathway, restoring the system to its basal, dark state, ready for signaling by the reappearance of light. Thus the three protein intermediates generated during periods of light — activated rhodopsin (R*), $G_{\alpha t}$·GTP, and activated PDE — must all be inactivated when the light goes off. Once these intermediates are inactivated, the concentration of cytoplasmic cGMP is restored rapidly to its dark level as cGMP is resynthesized by the guanylyl cyclase enzyme.

Termination of the Signal from Light-Activated Rhodopsin (R*) by Rhodopsin Phosphorylation and Binding of Arrestin

As noted above, the spontaneous cleavage of the covalent bond between an opsin and its all-*trans*-retinal and the release of the all-*trans*-retinal terminates signaling from that activated rhodopsin (R*) molecule. Refilling the retinal binding site with 11-*cis*-retinal restores the protein to the inactive (R) state. This process, called *dark adaptation*, is relatively slow compared to potentially very rapid changes in external illumination. Thus there are additional mechanisms that suppress the activity of activated rhodopsin more rapidly.

One important process that helps to terminate the response to light quickly is the phosphorylation of rhodopsin when it is in its activated (R*) form, but not its inactivated, or dark (R), form. The enzyme that catalyzes this phosphorylation is *rhodopsin kinase*, a member of the GRK family of kinases (see Figure 15-26a). Each opsin molecule has multiple principal serine and threonine phosphorylation sites on its cytosol-facing C-terminal segment; the more sites that are phosphorylated by rhodopsin kinase, the less R* is able to bind to and activate G_t.

The binding of arrestin to rhodopsin dramatically speeds up the inactivation process. Arrestin binds tightly to rhodopsin only when rhodopsin kinase has phosphorylated a sufficient number of C-terminal serines and threonines. Arrestin binding to the phosphorylated rhodopsin completely prevents its interaction with G_t, thus blocking formation of the active $G_{\alpha t}$·GTP complex and

further activation of PDE. The entire process of rhodopsin phosphorylation and its inactivation by arrestin is fast — it is completed within 50 milliseconds in mammals. The phosphorylated rhodopsin is restored to its original, light-sensitive state (R) during dark adaptation. During the dark, a specific rhodopsin phosphatase slowly removes the phosphates and 11-*cis*-retinal binds to opsin.

Termination of the Signal from Activated $G_{\alpha t}$·GTP by GTP Hydrolysis

$G_{\alpha t}$ automatically shuts itself off after a brief period: it contains an intrinsic GTPase activity that hydrolyzes the bound GTP to GDP, producing an inactive $G_{\alpha t}$·GDP complex. That inactive $G_{\alpha t}$·GDP reassociates with a $G_{\beta\gamma}$ and can no longer bind to a PDE γ subunit. The bound PDE γ subunits are released (see Figure 15-35, step **7**), and then rejoin the PDE α and β subunits to regenerate an inactive PDE $\alpha\beta\gamma_2$ tetramer (step **8**). Thus PDE rapidly loses its activity, and the cGMP concentration begins to rise to its levels before light induction. Through this process, the eye can respond quickly to changing patterns of light created by moving objects or a change in the direction of gaze.

The intrinsic GTPase activity of $G_{\alpha t}$ in rod cells is accelerated by the action of a specific heterodimeric GTPase-activating protein (GAP) that is recruited to the complex of the γ subunit of PDE and

$G_{\alpha t}$·GTP. As a result, the $G_{\alpha t}$ normally remains in the active GTP-containing state for only a fraction of a second. The components of this GAP are RGS9 and Gβ5 (see Figure 15-35, step **7**). Experiments with mice in which the gene encoding RGS9 had been knocked out showed that this protein is essential for normal inactivation of the signaling cascade in vivo. In individual mouse rod cells, the time required for recovery from a single flash of light increased from 0.2 second in the normal mouse to about 9 seconds in the RGS9-deficient mouse. This represents a 45-fold increase, attesting to the importance of RGS9 as a component of the $G_{\alpha t}$·GTP-GAP complex.

Rod Cells Adapt to Varying Levels of Ambient Light by Intracellular Trafficking of Arrestin and Transducin

When we move from bright sunlight into a dimly lit room, we are temporarily insensitive to low levels of light and initially cannot easily see the objects around us. However, after some time spent in the low-light conditions, our eyes adjust and we are better able to see and distinguish objects; we become more sensitive to lower levels of light. On the other hand, when we move quickly from a dimly lit room into bright sunshine, we are initially "blinded" by the bright light (hypersensitivity), but with time we become less sensitive (desensitized) and can once again see clearly. As the result of this process, called *light adaptation*, rod cells are able to perceive

clearly objects over a 100,000-fold range of ambient light levels, all the way from a dimly lit room to bright sunlight. This wide range of sensitivities is possible because it is the *difference* in light levels in the visual field, rather than the absolute *amount* of light absorbed, that is ultimately used by the brain to form visual images. Much of the visual adaptation occurs in the photoreceptor cells, which are able to adjust the rhodopsin-initiated signal transduction pathway (see Figure 15-34) to respond to low or high ambient light intensities.

In dark-adapted rod cells, 80–90 percent of the $G_{\alpha t}$ and $G_{\beta\gamma}$ transducin subunits are located in the outer segments, while fewer than 10 percent of the molecules of the inhibitor arrestin are located there (Figure 15-36). This spatial distribution allows maximal activation of the downstream effector PDE and thus maximal sensitivity to small changes in light. Exposure for 10 minutes to moderate daytime intensities of light causes a redistribution of these proteins such that over 80 percent of the $G_{\alpha t}$ and $G_{\beta\gamma}$ subunits move out of the outer segment into other parts of the cell, while over 80 percent of arrestin moves into the outer segment.

FIGURE 15-36 Schematic illustration of transducin and arrestin distribution in dark-adapted and light-adapted rod cells. (a) In the dark, most transducin (blue circles) is localized to the outer segment, while most arrestin (green circles) is found in other parts of the cell; in this condition, vision is most sensitive to very low light levels. (b) In bright light, little transducin is found in the outer segment, and abundant arrestin is found there; in this condition, vision is relatively insensitive to

small changes in light. The coordinated movement of these proteins contributes to our ability to perceive images over a 100,000-fold range of ambient light levels. See P. Calvert et al., 2006, *Trends Cell Biol.* **16**:560.

The mechanism by which these proteins move within the cell is not yet known, but most likely microtubule-attached motors carry the proteins into and out of the outer segment (see Chapter 18); note the microtubules in the diagram and micrograph in Figure 15-33. In bright light, the level of transducin, with its $G_{\alpha t}$ and $G_{\beta\gamma}$ subunits, is so reduced in the outer segment that G_t is simply not available for binding to and activation by rhodopsin. As a result, less PDE is activated. At the same time, the increase in the arrestin level in the outer segment means that any activated rhodopsin that has been phosphorylated by rhodopsin kinase will become rapidly inactivated. These protein movements are reversed when the ambient light level is lowered. Thus our visual system is desensitized in bright light by the drop in transducin level and the increase in arrestin level in the outer segment.

KEY CONCEPTS OF SECTION 15.6

Vision: How the Eye Senses Light

- Rhodopsin, the photosensitive GPCR in rod cells, comprises the protein opsin linked to 11-*cis*-retinal. The presence of light induces isomerization of the 11-*cis*-retinal moiety to all-*trans*-retinal. This changes the opsin conformation so that it activates the coupled heterotrimeric G protein transducin (G_t) by catalyzing exchange of free GTP for bound GDP on the $G_{\alpha t}$ subunit (see Figures 15-34 and 15-35).

- The effector protein in the rhodopsin pathway is PDE, which is activated by $G_{\alpha t} \cdot GTP$ binding to and releasing its inhibitory γ subunits. This enzyme reduces the cGMP level, and, as a result, cGMP-gated Na^{+}/Ca^{2+} channels close, the membrane becomes hyperpolarized, and the release of neurotransmitter decreases (see Figure 15-35).
- Several mechanisms act to terminate visual signaling: GAP proteins inactivate $G_{\alpha t} \cdot GTP$, and rhodopsin phosphorylation and binding of arrestin inhibit activation of transducin.
- Adaptation to a wide range of ambient light levels is mediated by movements of transducin and arrestin into and out of the rod-cell outer segment. Together, these two proteins modulate the ability of small increases in light levels to activate the downstream effector PDE, and thus the sensitivity of the rod cell to different ambient levels of light.

Review the Concepts

1. What common features are shared by most cell-signaling systems?
2. Signaling by soluble extracellular molecules can be classified as endocrine, paracrine, or autocrine. Describe how these three types of cellular signaling differ. Growth hormone is secreted from the pituitary, which is located at the base of the brain and acts through growth hormone receptors located on the liver. Is this an example of endocrine, paracrine, or autocrine signaling? Why?
3. A ligand binds two different receptors with a K_d value of 10^{-7} M for receptor 1 and a K_d value of 10^{-9} M for receptor

2. For which receptor does the ligand show the greater affinity? Calculate the fraction of receptors that have a bound ligand ($[RL]/R_T$) in the case of receptor 1 and receptor 2 if the concentration of free ligand is 10^{-8} M.

4. To understand how a signaling pathway works, it is often useful to isolate the cell-surface receptor and to measure the activity of downstream effector proteins under different conditions. How could you use affinity chromatography to isolate a cell-surface receptor? With what technique could you measure the amount of activated G protein (the GTP-bound form) in ligand-stimulated cells? Describe the approach you would take.
5. How do seven–transmembrane domain G protein–coupled receptors transmit a signal across the plasma membrane? In your answer, include the conformational changes that occur in the receptor in response to ligand binding.
6. Signal-transducing heterotrimeric G proteins consist of three subunits designated α, β, and γ. The G_α subunit is a GTPase switch protein that cycles between active and inactive states depending on whether it is bound to GTP or to GDP. Review the steps for ligand-induced activation of effector proteins mediated by the heterotrimeric G proteins. Suppose that you have isolated a mutant G_α subunit that has an increased GTPase activity. What effect would this mutation have on the G protein and the effector protein?
7. Explain how FRET could be used to monitor the association of $G_{\alpha s}$ and adenylyl cyclase following activation of the

epinephrine receptor.

8. Which of the following steps amplify the epinephrine signal response in cells: receptor activation of G protein, G protein activation of adenylyl cyclase, cAMP activation of PKA, or PKA phosphorylation of glycogen phosphorylase kinase (GPK)? Which change will have a greater effect on signal amplification: an increase in the number of epinephrine receptors or an increase in the number of $G_{\alpha s}$ proteins?
9. The cholera toxin, produced by the bacterium *Vibrio cholerae*, causes a watery diarrhea in infected individuals. What is the molecular basis for this effect of cholera toxin?
10. Both rhodopsin in vision and the muscarinic acetylcholine receptor in cardiac muscle are coupled to ion channels via G proteins. Describe the similarities and differences between these two systems.
11. In liver and muscle, epinephrine stimulation of the cAMP pathway activates glycogen breakdown and inhibits glycogen synthesis, whereas in adipose tissue, epinephrine activates hydrolysis of triglycerides, and in other cells, it causes a diversity of other responses. What step in the cAMP signaling pathways in these cells specifies the cell response?
12. Continuous exposure of a G protein–coupled receptor to its ligand leads to a phenomenon known as *desensitization*. Describe several molecular mechanisms for receptor desensitization. How can a receptor be reset to its original sensitized state? What effect would a mutant receptor

lacking serine or threonine phosphorylation sites have on a cell?

13. What is the purpose of A kinase–anchoring proteins (AKAPs)? Describe how AKAPs work in heart muscle cells.
14. Inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) are second messenger molecules derived from the cleavage of phosphatidylinositol 4,5-bisphosphate [$PI(4,5)P_2$] by activated phospholipase C. Describe the role of IP_3 in causing a rise in cytosolic Ca^{2+} concentration. How do cells restore resting levels of cytosolic Ca^{2+}? What is the principal function of DAG?
15. In Chapter 3, the Ca^{2+} of calmodulin EF hands for binding Ca^{2+} is given as 10^{-6} M. Many proteins have much higher affinities for their respective ligands. Why is the specific affinity of calmodulin important for Ca^{2+} signaling processes such as that initiated by production of IP_3?
16. Most of the short-term physiological responses of cells to cAMP are mediated by activation of PKA. Another common second messenger is cGMP. What are the targets of cGMP in rod cells?

CHAPTER 16

Growth Factor and Cytokine Signaling Pathways That Control Gene Expression

Courtesy of Christian Petersen and Peter Reddien, MIT, Whitehead Institute.

A planarian with multiple heads. Several hormones and their receptors regulate the regeneration of complex body parts in wounded planaria; the extracellular signaling protein Wnt promotes tail regeneration and inhibits head regeneration. In an experiment, the gene encoding *beta-catenin-1*, an essential protein in the Wnt signal transduction pathway, was inhibited by feeding animals an inhibitory double-stranded RNA. During the subsequent

month, normal uninjured animals developed heads around their periphery in a process induced by small wounds caused by defects in stem-cell mediated tissue turnover and repair; the complete absence of a Wnt signal at these wounds promotes formation of a head.

16.1 Growth Factors and Their Receptor Tyrosine Kinases
16.2 The Ras/MAP Kinase Signal Transduction Pathway
16.3 Phosphoinositide Signal Transduction Pathways
16.4 Cytokines, Cytokine Receptors, and the JAK/STAT Signaling Pathway
16.5 The TGF-β Family of Growth Factors, Their Receptor Serine Kinases, and the Smad Transcription Factors They Activate
16.6 Signal Transduction Pathways That Utilize Regulated, Site-Specific Protein Cleavage: Notch/Delta and EGF Precursors
16.7 Signal Transduction Pathways That Utilize Proteasomal Degradation of Signaling Components: Wnt, Hedgehog, and the Many Hormones That Activate NF-κB

Hundreds of extracellular signaling molecules regulate the growth and fate of cells and in this way control the development of all metazoans; these signaling molecules can have both short- and long-term effects on cells. Short-term effects are usually triggered by modification of existing enzymes or other proteins, as we saw in Chapter 15. Long-term changes in cell function, however, require changes in gene expression. Thus many extracellular signaling molecules alter the expression of genes and in doing so can alter cell division and cell differentiation. For example, signaling molecules called *cytokines* induce the body's production of red blood cells, white blood cells, and platelets. Once differentiated, cells respond to their environment by changing their shape, metabolism, or movement. Here again, extracellular signaling molecules may lead

to changes in gene expression. In response to infection, for example, several hormones activate or repress the expression of several hundred genes in immune system cells that carry out multiple responses to infection. Given the extensive role of gene transcription in mediating critical aspects of development, metabolism, and movement, it is not surprising that mutations in such signaling pathways cause many human diseases, including cancer, diabetes, and immune-system disorders.

In this chapter, we explore the main groups of hormones, receptors, and their associated intracellular signal transduction pathways that cells use mainly to influence gene expression. In eukaryotes, there are about a dozen classes of highly conserved cell-surface receptors, and these receptors activate several types of highly conserved and often complex intracellular signal transduction pathways, leading to both short-term and long-term effects. These pathways have been conserved throughout evolution and operate in much the same manner in flies, worms, planaria, mice, and humans; their commonalities have enabled researchers to study them in a variety of experimental systems. For instance, the signaling protein Hedgehog (Hh) and its receptor were first identified in fruit fly *(Drosophila)* mutants that had impaired development. Subsequently, the human and mouse homologs of these proteins were cloned and shown to participate in a number of important signaling events during cell differentiation, resulting in the discovery that abnormal activation of the Hh pathway occurs in several human tumors.

Despite the complexity of many of these signal transduction pathways, there are features common to many of them. We learned about some in our study of GPCR signaling, and we will encounter others in the following sections. Signal transduction pathways that regulate gene expression act through transcription factors that switch genes on or off. In non-stimulated cells, most regulated transcription factors are sequestered in the cytosol, unable to move into the nucleus, bind to DNA, or affect gene expression. Activation of the relevant signal transduction pathway triggers transport of the transcription factor into the nucleus, in some cases by releasing it from an inhibitory complex in the cytosol, in others by unmasking a nuclear localization sequence. Alternatively, a kinase in the signal transduction pathway may phosphorylate the transcription factor, converting it into an active form that is able to bind to DNA. Another common theme is negative feedback regulation through changes in gene expression; a regulated transcription factor may induce synthesis of proteins that repress or dampen a signal transduction pathway — preventing overstimulation of the cell.

We begin this chapter with a large class of receptors — the Receptor Tyrosine Kinases (RTKs; Section 16.1) — that are activated by a large group of protein growth factors. Ligand binding to the extracellular domain induces two monomers to bind together as a dimer, activating a protein kinase contained in its cytosolic domain (Figure 16-1a). One important RTK signaling pathway includes the activation of the small GTP-binding protein termed Ras; Ras in turn activates a cascade of protein kinases in which one kinase activates another —

the Ras/MAP Kinase Pathway (Figure 16-1a, Pathway A; Section 16.2). The final kinase phosphorylates and activates one or more transcription factors (Tfs).

FIGURE 16-1 Common types of cell-surface receptors and signal transduction pathways that regulate gene expression. (a) Signal transduction pathways activated by receptor tyrosine kinases (RTKs) and cytokine receptors. The cytosolic domain of RTKs contains an intrinsic protein tyrosine kinase domain; the cytosolic domain of cytokine receptors bind a separate protein tyrosine kinase. In the absence of ligand these receptors generally exist as monomers that have poor kinase activity. Binding of ligands to the extracellular domains of these receptors triggers dimerization of two monomers and activation of the tyrosine kinase and phosphorylation of several tyrosine residues in the receptor's cytosolic domain. The resulting phosphotyrosines function as docking sites for binding and activating several downstream signal-transducing proteins. Pathway A: Binding of one type of adapter protein (e.g., GRB2) to an activated receptor leads to activation of the small GTP-binding "switch" protein Ras (see Section 16.2). Signal transduction pathways downstream of Ras involve several kinases; in these MAP kinase pathways, one kinase phosphorylates and thus activates the activity of another. This leads to phosphorylation and activation of transcription factors, which are often different in different cells. Pathways B and C: Two signal transduction pathways that involve phosphoinositides are triggered by recruitment of phospholipase C and PI-3 kinase, respectively, to the plasma membrane (see Section 16.3). Elevated levels of Ca^{2+} and activated protein kinase B modulate the activity of transcription factors as well as of cytosolic proteins that are involved in metabolic pathways or cell movement or shape change. Pathway D: In a pathway mainly employed by cytokine receptors, a STAT transcription factor binds to the activated receptor, becomes phosphorylated, dimerizes, moves to the nucleus, and directly activates transcription. (b) Other common types of cell-surface receptors and signal transduction pathways. Pathway A: Many GPCRs activate the heterotrimeric GTP-binding $G_{\alpha,s}$ protein, ultimately leading to activation of protein kinase A, and phosphorylation and activation of transcription factors such as CREB. Pathway B: The cytosolic domains of receptors for the TGF-β family of signaling proteins contain a serine-threonine kinase, which directly phosphorylates and activates a member of the Smad class of transcription factors, unmasking a nuclear localization signal. Pathway C: Binding of a Delta ligand to the extracellular domain of a

member of the Notch family of receptors triggers proteolytic cleavage of the receptor, releasing its cytosolic domain, which moves into the nucleus and regulates gene expression. Pathway D: Signal transduction pathways activated by binding of members of the Wnt, Hedgehog, or Interleukin 1 (IL-1) families of ligands to their respective receptors lead to ubiquitination and degradation of components of multiprotein complexes in the cytosol, releasing a transcription factor that then translocates into the nucleus.

Alternatively, RTKs can initiate signal transduction pathways containing phosphorylated inositols that often although not always lead to changes in gene expression. In Chapter 15 we saw one that leads to an elevation in the concentration of Ca^{2+} in the cytosol (Figure 16-1a, Pathway B). Depending on the type of cell, this pathway triggers processes as diverse as protein secretion and cell migration. RTKs also induce other signaling pathways involving phosphorylated inositols that activate yet other protein kinases, including Protein Kinase B, that in turn alter gene expression to regulate cellular metabolism and cell death (Figure 16-1a, Pathway C; Section 16-3).

Cytokines activate a distinct class of signaling receptors. The cytokines form a large family of protein hormones that regulate, for example, the formation and function of all types of blood cells, including all of the many kinds of cells that compose our immune system (Chapter 24). Cytokine receptor proteins are similar to RTKs in that ligand binding leads to the activation of a protein tyrosine kinase (JAK), although in this case the kinase is a separate protein tightly associated with the receptor's cytosolic domain. Cytokine

receptors and RTKs activate many of the same signal transduction pathways (see Figure 16-1a), and in Section 16-4 we learn how a JAK kinase directly phosphorylates a STAT transcription factor (Figure 16-1a, Pathway D). Phosphorylation leads to the exposure of a nuclear localization signal that guides the transcription factor to the nucleus.

The large TGF-β family of extracellular signaling proteins acts to regulate many developmental pathways. Like RTKs, these structurally distinct receptors employ activation of a kinase that is part of their cytosolic domain. The activated kinase directly phosphorylates transcription factors in the Smad family of DNA-binding proteins (Figure 16-1b, Pathway B, and Section 16.5). In this case, phosphorylation unmasks a nuclear localization signal that allows the transcription factor to move directly to the nucleus.

Not all of the signaling receptors described in this chapter lead to the activation of protein kinases or GTP-binding proteins in the earliest steps of their signal transduction pathways. For example, binding of a ligand to the extracellular domain of certain receptors, such as Notch, triggers proteolytic cleavage of the receptor itself, releasing the cytosolic domain. The released domain is a transcription factor that travels into the nucleus and interacts with other transcription factors to alter gene expression (Figure 16-1b, Pathway C, and Section 16-6).

Finally, we discuss several different pathways in which binding of the ligand to its receptor ultimately leads to ubiquitination and degradation of one or more proteins in a multiprotein cytosolic complex, consequently releasing a transcription factor that is part of the complex and that then translocates into the nucleus and affects gene expression (Figure 16-1b, Pathway D). These include signaling pathways activated by the Wnt and Hedgehog signaling proteins, and others downstream of several types of receptors that all lead to activation of the NF-κB transcription factor.

As with GPCRs, many receptors discussed in this chapter are expressed in multiple types of body cells, but activation of these receptors by the same hormone triggers induction (or repression) of very different sets of genes in different cell types. As we learned in Chapter 8, the epigenetic state of the cell is determined by its developmental history. Whether a transcription factor activated by a cell-surface receptor induces (or represses) a particular gene in a particular cell depends, first (Figure 16-2), on the epigenetic state of the gene: whether the gene is in an active "open" chromatin conformation, and therefore accessible to binding by the transcription factor, or in a silenced "closed" state that is not accessible by the transcription factor. In other words, a given transcription factor can potentially bind to multiple gene regulatory sites in chromosomal DNA, but in any given cell type only a fraction of these sites will be accessible for binding.

FIGURE 16-2 Induction of a particular gene by a transcription factor depends on DNA-binding sites for the factor, on the gene's epigenetic state, and on the presence of master transcription factors and other nuclear proteins. Any given activated transcription factor has multiple sites on the chromosomal DNA to which it can potentially bind (green), but in any given cell it will bind only to those sites that are in an "open" chromatin conformation and in which specific master transcription factors or other cell-specific proteins (blue and red, respectively) are bound to adjacent sites on the DNA; together these proteins activate (or repress) expression of the adjacent gene. Other potential transcription-factor binding sites are adjacent to binding sites for other master transcription factors (yellow) that are not expressed in this cell type, and thus the activated transcription factor will not bind to those sites.

Additionally, many cell types express one or more *master transcription factors* that determine the identity and developmental fate of the cell; a recent finding is that many transcription factors

activated by cell-surface receptors bind to chromosomal DNA at regulatory sites — mainly enhancers — adjacent to these master factors, and together these transcription factors induce (or repress) cell-specific genes (see Figure 16-2).

No cell-surface receptor, and no signal transduction pathway, works in isolation. Expression of many if not most genes in metazoans are regulated by multiple transcription factors, and these in turn are activated or repressed by different intracellular signaling pathways, each of which can be regulated by multiple extracellular signals. An emerging subfield of molecular cell biology — systems analysis — uses a combination of experimental and computational analyses to understand how cells of different types integrate these signals over time. For example, in Chapter 21 we consider how multiple hormones and multiple signal transduction pathways in different types of cells regulate the body's needs for the key metabolites glucose and fatty acids.

16.1 Growth Factors and Their Receptor Tyrosine Kinases

The extracellular signaling molecules that activate receptor tyrosine kinases (RTKs) constitute a large class of soluble and membrane-bound protein hormones, including many that were initially identified because they stimulate the growth of specific types of cells (hence the name *growth factor*). Those RTK ligands, such as nerve growth factor (NGF), platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), and epidermal growth factor (EGF), trigger proliferation of cells that bear a cognate receptor. Others, such as insulin, regulate expression of multiple genes that control sugar and lipid metabolism in liver, muscle, and adipose (fat) cells. The large family of ephrins play critical roles in regulating the migration of many nerve cell axons to their target destinations (see Chapter 23). Many RTKs and their ligands were first identified in studies of human cancers, in which mutant forms of growth-factor receptors stimulate cell proliferation even in the absence of the growth-factor ligand. The mutation locks the receptor conformation in a state such that the kinase is permanently active, even if the ligand is not present (*constitutively* active; see Chapter 25). Other RTKs were uncovered during analysis of developmental mutations that lead to blocks in differentiation of specific cell types in *Caenorhabditis elegans, Drosophila*, and mice.

Binding of Ligand to the Extracellular Domain of an RTK Leads to Dimerization and Activation of Its Intrinsic Cytosolic Tyrosine Kinase

All RTK proteins have four essential components: an extracellular domain containing a ligand-binding site, a single hydrophobic transmembrane α helix, a cytosolic segment that includes a domain with protein tyrosine kinase activity, and a C-terminal segment that contains tyrosine residues that become phosphorylated by the receptor's own kinase (Figure 16-3). Most RTKs are monomeric, and ligand binding to the extracellular domain induces two monomers to join together as a dimer.

FIGURE 16-3 General structure and activation of receptor tyrosine kinases (RTKs). The cytosolic domain of RTKs contains an intrinsic protein tyrosine kinase domain. In the absence of ligand (step 1), RTKs generally exist as monomers with poor kinase activity. Binding of two ligands to the extracellular domains of two RTKs forms or stabilizes an activated dimeric receptor. This brings together two poorly active kinases such that each

one phosphorylates the other on a tyrosine residue in the activation loop (step **2**). Phosphorylation increases the activity of the kinase by causing the loop to move out of the kinase catalytic site, thus increasing the ability of ATP and/or the protein substrate to bind (see Chapter 3). The activated kinase then phosphorylates several tyrosine residues in the receptor's cytosolic domain (step **3**). The resulting phosphotyrosines function as docking sites for SH2 and other binding domains on downstream signal-transducing proteins, as summarized in Figure 16-1a.

RTK activation and signaling can be summarized as follows: in the resting, unstimulated (no ligand bound) state, the intrinsic kinase activity of an RTK is very low (Figure 16-3, step **1**). Like most other kinases, the cytosolic kinase domain of an RTK contains a flexible domain termed the **activation loop**. In the resting state, the activation loop is not phosphorylated and assumes a conformation that blocks kinase activity. In some receptors (e.g., the insulin receptor), this loop prevents binding of ATP. In others (e.g., the FGF receptor), it prevents binding of substrate. Binding of ligand causes a conformational change that promotes the dimerization of the RTK. The extracellular domains of two RTK monomers join, which brings their transmembrane segments — and therefore their cytosolic domains — close together and results in activation of the tyrosine kinases. For most, but not all, RTKs, the weakly active kinase in each subunit is thought to phosphorylate a key tyrosine residue in the activation loop of the other subunit (Figure 16-3, step **2**). This phosphorylation leads to a conformational change in the activation loop that unblocks the kinase active site, reducing the K_d for either ATP or the substrate to be phosphorylated and greatly enhances kinase activity (see Chapter 3). The strongly active kinase then

phosphorylates additional tyrosine residues in the cytosolic domain of the receptor (Figure 16-3, step **3**). These phosphotyrosine residues serve as binding sites for proteins that then activate several signal transduction pathways (see Figure 16-1a), each of which will be detailed in subsequent sections of this chapter.

Although dimerization is a necessary step in the activation of all RTKs, functional dimers can be formed in multiple ways, as we shall see. For example, many receptors are dimerized in a manner similar to the fibroblast growth factor (FGF) receptor (Figure 16-4), in which each of two FGF ligands binds simultaneously to the extracellular domains of both subunits of the dimerized receptor, stabilizing the dimer. An additional feature is that FGF binding, and thus FGF receptor dimerization, is enhanced by the additional binding to both the ligand FGF and its receptor of the negatively charged polysaccharide heparan sulfate (see Figure 16-4), which is a component of some cell-surface proteins and of the extracellular matrix (see Chapter 20). The participation of the heparan sulfate is essential for efficient receptor activation; we see later (Section 16.5) that binding of other hormones to components of the extracellular matrix is also essential for their signaling functions.

FIGURE 16-4 Structure of the extracellular domains of the active dimeric fibroblast growth factor (FGF) receptor, stabilized by binding of two ligands and by heparan sulfate. Shown here are side and top-down views of the complex comprising the extracellular domains of two FGF receptor (FGFR) monomers (purple and violet), two bound FGF molecules (red), and two short

heparan sulfate chains that are bound tightly to FGF. (a) In the side view, the upper domain of one receptor monomer (purple) is seen situated behind that of the other (violet); the plane of the plasma membrane is at the bottom. A small segment of the receptor's extracellular domain connects to the membrane-spanning α-helical segment of each of the two receptor monomers (not shown) that protrude downward into the membrane. (b) In the top view, the heparan sulfate chains are seen threading between and making numerous contacts with the upper domains of both receptor monomers. These interactions enhance binding of the FGF ligand to the receptor and receptor dimerization.

[Data from J. Schlessinger et al., 2000, *Mol. Cell* **6**:743, PDB ID 1fq9.]

Yet other RTKs, such as the insulin receptor, form disulfide-linked dimers even in the absence of hormone; binding of ligand to this type of *pre-dimerized* but inactive RTK alters the conformation of the dimer in such a way that the receptor's kinase becomes activated (Figure 16-5). In the absence of insulin, the structure of the dimeric receptor's extracellular domain forces the weakly active cytosolic kinase domains to be far apart, unable to phosphorylate and thus activate each other. Upon insulin binding, the receptor's extracellular domain converts from an inverted U-shape into a T-shaped conformation that brings the transmembrane domains, and thus the kinase domains, together, presumably facilitating phosphorylation of the activation loop in the tyrosine kinase domain of one receptor by the kinase in the other.

FIGURE 16-5 Insulin-induced activation of the insulin receptor. (a) Schematic cartoon showing the extracellular domain (ECD), transmembrane domain (TMD), and tyrosine kinase domain (TKD) as well as a structural model of the full-length human insulin receptor in the absence of insulin. The receptor is produced as a single polypeptide chain that undergoes cleavage in the Golgi complex; the two resulting subunits, α and β, are linked together by a disulfide bond, as are the two α subunits in a dimer. (b) Electron microscopic views of single insulin receptors reconstituted in tiny lipid discs, both in the absence and presence of insulin. (c) Cartoon illustrating the ligand (green) binding–induced conformational change in the extracellular domain of the insulin receptor and its coupling to the transmembrane domains (TMDs) with concomitant activation of the tyrosine kinase domains by phosphorylation. In the absence of insulin, the extracellular domain adopts a symmetric inverted U-shaped conformation; upon insulin binding, the extracellular domain is converted into a T-shaped conformation that brings the transmembrane domains together, presumably facilitating phosphorylation of the activation loop of one kinase by the poorly active kinase of the other (trans-phosphorylation), leading to activation of both tyrosine kinase domains.

This last example highlights the fact that simply having two identical receptor monomers in close contact is not sufficient for receptor activation — the proper conformational changes must accompany

receptor dimerization. Once an RTK converts into a functional state in a dimer, its associated tyrosine kinase becomes activated.

Homo- and Hetero-Oligomers of Epidermal Growth Factor Receptors Bind Members of the Epidermal Growth Factor Family

During evolution, the genes encoding some growth factors and their receptors underwent duplication and diverged to encode similar, but distinct, proteins with distinct functions. For example, in humans there are 22 FGF-related and 4 FGF receptor-related genes with many different functions. There are also multiple members of the *epidermal growth factor (EGF)* and EGF receptor families that have been studied intensively because of their involvement in many human diseases. Drugs targeting EGF receptors that are overproduced in tumors or that have undergone mutations that cause their kinase domains to be active even in the absence of a hormone signal are used to treat many cancers, as we learn in Chapter 25. The first known member of this family of hormones, epidermal growth factor, was originally identified by Stanley Cohen as a small protein that stimulated the early opening of eyelids in a baby mouse; it is now known to stimulate the proliferation of many types of epithelial cells. For this research and the parallel discovery

of nerve growth factor, Cohen and Rita Levi-Montalcini were awarded Nobel Prizes.

Four related EFG receptors participate in signaling by the many members of the epidermal growth factor family of signaling molecules. In the mouse these receptors are termed Erb-B1, 2, 3, and 4. In humans these receptors are called **HER** (*h*uman *e*pidermal growth factor *r*eceptor) 1, 2, 3, and 4, respectively.

EGF Receptor Homodimers

In the resting state, the majority of EGF receptor molecules are monomeric. We first consider the activation of the EGF receptor HER1 (Erb-B1). HER1 directly binds EGF as well as six other members of the EGF family; binding of any of these ligands leads to formation of a homodimer (homodimerization) of the HER1 extracellular domain (Figure 16-6). Binding of EGF binding triggers a dramatic conformational change in the extracellular domain of HER1, exposing a portion of the receptor that is inaccessible in the inactive monomer, termed the *dimerization arm*. The dimerization arms from two receptor monomers then bind tightly together, forming a receptor homodimer that is further stabilized by interactions between another extracellular domain (domain IV) in each of the two receptors. Several members of the EGF family — neuregulins 1, 2, 3, and 4 — bind to HER4 that, like HER1, can also

form homodimers. As detailed below, formation of a receptor dimer triggers activation of the kinase domain.

FIGURE 16-6 Ligand-induced dimerization of HER1, a human receptor for epidermal growth factor (EGF). (a) The extracellular region of all EGF receptors contains four domains: domains I (blue) and III (yellow) are closely related in sequence, as are domains II (green) and IV (red). In the absence of bound EGF, the receptor is mostly monomeric and the intracellular kinase is inactive. The extracellular region adopts a configuration in which the β-hairpin from domain II that forms the *dimerization arm* binds to domain IV of the same receptor molecule. (b) EGF, as well as the six other listed members of the EGF family, binds simultaneously to domains I and III; binding induces a major conformational change in the extracellular domain, exposing the dimerization arm of domain II. (c) Dimerization of two identical ligand-bound receptor monomers in the plane of the membrane occurs primarily through interactions between the dimerization arms of the two receptors.

[Data from H. Ogiso et al., 2002, *Cell* **110**:775, PDB ID 1ivo.]

EGF Receptor Heterodimers with HER2

Remarkably, although one of the EGF receptors, HER2 (mouse Erb-B2), cannot bind any ligand, it participates in signaling by forming heterodimers with HER1, HER3, or HER4 when they are bound to their respective ligands. HER2 can form heterodimers with these other EGF receptors because it adopts an active conformation with its dimerization arm always accessible for binding to the dimerization arms of ligand-bound receptors. Thus, by HER2 forming heterodimers, its kinase domain becomes activated and in so doing it facilitates signaling by all EGF family members that bind to one of the other three EGF receptors (Figure 16-7).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 16-7 The HER family of receptors and their ligands. Humans and mice express a family of four receptor tyrosine kinases, denoted HER1, 2, 3, and 4 in humans and Erb-B1, 2, 3, and 4 in mice and other animals. Only the extracellular domains of these receptors are depicted here. These receptors bind epidermal growth factor (EGF) and the other EGF family

members: heparin-binding EGF (HB-EGF), transforming growth factor α (TGF-α), amphiregulin (AREG), epiregulin (EREG), epigen (EPGN), betacellulin (BTC), and the four neuregulins (NRG1–4). Notice that Erb-B2 (HER2), which does not directly bind a ligand, exists in a conformation that is very similar to that of the activated Erb-B1 with a bound EGF. Erb-B2 can form a heterodimer with ligand-activated Erb-B1, 3, or 4; thus Erb-B2 facilitates signaling by all EGF family members. Erb-B3 (HER3) has a very poorly active kinase domain and can signal only when complexed with Erb-B2.

Ogiso et al., 2002, *Cell* **110**:775, PDB ID 1ivo.]

HER3 is an EGF receptor that can bind ligands but lacks a functional kinase domain. HER3 can still participate in signaling; after binding a ligand, it heterodimerizes with HER2 and activates the HER2 kinase. Later we describe how the active kinases in the receptor cytoplasmic domains mediate downstream signal transduction pathways.

An increase in the numbers of HER2 molecules on the cell surface makes a cell more sensitive to signaling by many EGF family members, because the greater number of HER2 receptors enhances the rate and extent of formation of signaling heterodimers following binding of a member of the EGF family to HER1, HER3, or HER4. As we learn in Chapter 25, in about 25 percent of breast cancers the tumor cells have multiple copies of the *HER2* gene and thus elevated levels of HER2. Cells that overproduce HER2 are hypersensitive to ambient levels of all members of the EGF family of hormones, levels

that normally would not lead to activation of many receptors. As a consequence, at even low levels EGF family members can stimulate growth of these tumor cells inappropriately. Monoclonal antibodies that bind HER2 and thereby block signaling by EGF have proved useful in treatment of breast and other tumors that overexpress HER2. ■

Ligand Binding to the EGF Receptor and Receptor Dimerization Results in the Formation of an Active Asymmetric Kinase Domain Dimer

In the case of most receptor tyrosine kinases, the kinase domain is activated by phosphorylation of a tyrosine in the activation loop following formation of a receptor dimer. In contrast, loop phosphorylation is not necessary for initial activation of the kinase domains of the EGF receptors, though it is important for full activation. The mechanism of activation was uncovered through structural studies of the receptor cytosolic domain in both the active and inactive states.

The kinase domains are separated from the transmembrane segment by a so-called juxtamembrane segment (Figure 16-8). As we learned in Chapters 3 and 15, kinase domains typically contain two regions termed the *N* and *C lobes*. In the inactive, monomeric state

of the EGF receptor, the activation loop is situated in the active site of the kinase near the interface of the N and C lobes, blocking the site's activity; in this way the kinase is maintained in the inactive or "off" state (Figure 16-8, *left*). Receptor dimerization brings the kinase domains of the two subunits close together, so that the C lobe of one kinase domain (called the *donor*) binds to the N lobe of the other kinase domain (the *acceptor*), producing what is called an *asymmetric kinase dimer* (Figure 16-8, *right*). The binding of the two lobes changes the conformation of the N lobe of the acceptor kinase, displacing the activation loop and activating the kinase activity of the acceptor domain, thereby initiating intracellular signal transduction.

FIGURE 16-8 Activation of the EGF receptor by EGF results in the formation of an active asymmetric kinase domain dimer. In the inactive, monomeric state, the activation loop is

positioned in the kinase active site, blocking substrate binding and thus inhibiting kinase function. Receptor dimerization generates an asymmetric kinase dimer such that the C lobe of the donor kinase binds to the N lobe of the acceptor kinase in the opposite receptor; the dimer is stabilized by interactions between the juxtamembrane segments of the two receptors. These interactions cause a conformational change that pushes out the activation loop from the kinase site of the acceptor kinase, activating its kinase activity. The active acceptor kinase then phosphorylates tyrosine residues in the C-terminal segments of both receptor cytosolic domains.

[EGF receptor data from H. Ogiso et al., 2002, *Cell* **110**:775, PDB ID 1ivo; and K. M. Ferguson et al., 2003, *Mol. Cell.* **11**:507, PDB ID 1nql. Asymmetric kinase dimer data from E. Kovacs et al., 2015, *Annu. Rev. Biochem.* **84**:739.]

Thus evolution has produced many variations on the theme of ligand-induced RTK signaling: RTKs are activated by dimerization, but different receptors use different mechanisms to accomplish this. Similarly, kinases become activated by movement of the activation loop away from the kinase catalytic site, but, again, different receptors use different mechanisms to accomplish this.

Signal Transduction After Activation of RTKs: Phosphotyrosine Residues on the Receptor Are Binding Surfaces for Multiple Proteins with SH2 Domains

Once the RTK kinases become activated, they phosphorylate several tyrosine residues on their cytosolic domains (see Figures 16-3 and 16-8). Each of these phosphotyrosine residues, together with a few

adjacent residues, serve as binding sites for signal-transducing proteins that have conserved phosphotyrosine-binding domains (see Figure 16-1a). The recruitment of each signal-transducing protein to the activated receptor sets off a specific subsequent signal transduction pathway.

There are several classes of phosphotyrosine-binding domains; one is called the *SH2 domain*. An SH2 domain is able to bind to a short target sequence of polypeptide that contains a phosphotyrosine. The SH2 domains in different signal-transducing proteins have very similar three-dimensional structures, but each binds to a distinct, short target sequence of amino acids adjacent to a specific phosphotyrosine residue (often abbreviated "pY"). The unique amino acid sequence of each SH2 domain determines the specific target sequence to which it binds (Figure 16-9). Each SH2 domain contains a site for binding the phosphotyrosine and sites for binding the side chains of the adjacent residues in that SH2's target sequence.

FIGURE 16-9 Surface model of an SH2 domain bound to a phosphotyrosine-containing peptide. The peptide bound by this SH2 domain, part of the Src tyrosine kinase, is shown in stick form (blue backbone with red oxygen atoms). This SH2 domain binds strongly to short target peptides containing a critical four-residue core sequence: phosphotyrosine (Tyr_0 and $\mathrm{OPO_3}^-$)–glutamic acid (Glu_1)–glutamic acid (Glu_2)–isoleucine (Ile_3). Binding resembles the insertion of a two-pronged plug — the phosphotyrosine and isoleucine side chains of the peptide — into a two-pronged socket in the SH2 domain. The two glutamate residues are bound to sites on the surface of the SH2 domain between the two sockets. Other SH2 domains bind phosphotyrosine residues surrounded by other sequences of amino acids.

[Data from G. Waksman et al., 1993, *Cell* **72**:779, PDB ID 1sps.]

As an example, consider the protein in which SH2 domains were first identified, the tyrosine kinase called *Src* (Src is an acronym for a *sarcoma* tumor). *A* mutant form of the *src* gene, which inappropriately activates a downstream signal transduction pathway, was originally found incorporated in the *Rous sarcoma virus* that in chickens causes sarcomas (a muscle tumor, as Chapter 25

details). The SH2 domain of the Src tyrosine kinase binds strongly to any peptide containing the four-residue sequence: phosphotyrosine–glutamic acid–glutamic acid–isoleucine (single letter code: pY-E-E-I, see Figure 16-9). These four amino acids make intimate contact with the peptide-binding site in the Src SH2 domain. Binding resembles the insertion of a two-pronged plug — the phosphotyrosine and isoleucine side chains of the peptide — into a two-pronged socket in the SH2 domain. The two glutamic acids fit snugly onto the surface of the SH2 domain between the phosphotyrosine binding socket and the hydrophobic socket that binds the isoleucine residue. The specificity of SH2 domains for their target sequence plays an important role in determining which SH2-domain-containing signal-transducing proteins bind to which receptors and thus which signal transduction pathways are activated.

Receptor-Mediated Endocytosis and Lysosomal Degradation Squelch Signaling from RTKs

In Chapter 15 we emphasized that, to prevent overstimulation, cells must be able to suppress or even turn off their signal transduction pathways. In addition, once the cell has adequately responded to the signal, or when the signal has been removed, it is important to prevent any further cellular response. Suppression of signaling from

RTKs is common, and different mechanisms have evolved to accomplish this task.

For example, phosphotyrosine phosphatases continuously hydrolyze the bonds linking phosphates to tyrosine residues on the receptor, reducing the ability of activated RTKs to bind proteins containing phosphotyrosine-binding domains and thus diminishing the activation of signal transduction pathways. A second mechanism — receptor-mediated endocytosis followed by receptor degradation in lysosomes — is another common method for dampening RTK signal transduction.

Treatment of cells with ligand often reduces the number of available cell-surface receptors, so that the cells have a less robust response to continuous exposure to a given concentration of ligand than they did before ligand addition. This *desensitization response* helps prevent inappropriately prolonged receptor activity. In the absence of EGF, for instance, cell-surface HER1 receptors are relatively long-lived, with an average half-life of 10–15 hours. Unbound receptors are internalized via clathrin-coated pits into endosomes at a relatively slow rate, on average once every 30 minutes, and are often recycled rapidly to the plasma membrane so that in the absence of ligands there is little reduction in the total number of surface receptors. Following binding of an EGF ligand, the rate of endocytosis of HER1 is increased about tenfold, and only a fraction of the internalized receptors return to the plasma membrane; the rest are degraded in

lysosomes. Each time a HER1–EGF complex is internalized through endocytosis (see Figure 14-29), the receptor has about a 20–80 percent chance of being degraded, depending on the cell type. In epithelial cells exposed to high levels of EGF, for example, almost all cell-surface EGF receptor molecules are internalized and degraded, markedly reducing the cell's sensitivity to EGF. In this way, prolonged treatment with EGF desensitizes the cell to that hormone. If the EGF is removed, newly synthesized receptors will eventually replenish the cell surface and allow the cell to respond to a second treatment of EGF.

Several processes influence whether surface receptors internalized in endosomes are recycled to the plasma membrane or transported to lysosomes for degradation. One is covalent modification by the small protein ubiquitin (see Chapter 3). The enzyme c-Cbl adds a single ubiquitin to a given lysine of a protein, a process called *monoubiquitinylation*. There is a strong correlation between the extent of monoubiquitinylation of the HER1 cytosolic domain and HER1 degradation; such monoubiquitinylation also occurs to other ligand-activated RTKs. The enzyme c-Cbl, which is an E3 ubiquitin ligase (see Figure 3-32), contains a domain that binds directly to phosphorylated EGF receptors, and a RING finger domain, which recruits ubiquitin-conjugating enzymes and mediates transfer of ubiquitin to the receptor. The ubiquitin functions as a tag on the receptor that stimulates its incorporation from endosomes into multivesicular bodies (see Figure 14-32) that are ultimately engulfed

by and degraded in lysosomes. A role for c-Cbl in EGF receptor trafficking emerged from genetic studies in *C. elegans*, which established that c-Cbl negatively regulates the function of the nematode EGF receptor (Let-23), probably by inducing its degradation. Similarly, knockout mice lacking c-Cbl show hyperproliferation of mammary gland epithelia, consistent with a role of c-Cbl as a negative regulator of EGF signaling.

Interestingly, the other EGF family receptors — HER2, HER3, and HER4 — do not undergo internalization after exposure to ligand, an observation that emphasizes how each receptor evolved to be regulated in its own appropriate manner.

KEY CONCEPTS OF SECTION 16.1

Growth Factors and Their Receptor Tyrosine Kinases

- Receptor tyrosine kinases, which bind to peptides and signaling proteins such as growth factors and insulin, may exist as preformed dimers or dimerize when ligands bind. Ligand binding triggers conformational changes leading to formation of functional dimeric receptors, a necessary step in activating the receptor's kinase domain. Different receptors accomplish this function in different ways (see Figures 16-3 to 16-7).
- Activation of many RTKs leads to phosphorylation of the activation loop in the protein tyrosine kinase that is an intrinsic part of the cytoplasmic domain, enhancing its catalytic activity (see Figure 16-3). The activated kinase then phosphorylates tyrosine residues in the receptor's cytosolic domain and in other protein substrates.
- Humans express many RTKs, four of which (HER1–HER4) define the family of epidermal growth factor receptors that mediates signaling from the many members of the epidermal growth factor family of signaling molecules (see Figure 16-7). One of these receptors, HER2, does not bind ligand; it forms active heterodimers with ligand-

bound monomers of the other three HER proteins. Overexpression of HER2 is implicated in many breast cancers.

- In RTKs, short amino acid sequences containing a phosphotyrosine residue are bound by signal-transducing proteins with conserved SH2 domains. The sequence of amino acids surrounding the phosphorylated tyrosine determines which SH2 domain will bind to it (see Figure 16-9). Such protein-protein interactions are important in determining specificity in many signaling pathways (see Figure 16-3).
- Endocytosis of receptor-ligand complexes and their degradation in lysosomes is a principal way of reducing the number of receptor tyrosine kinases on the cell surface and thus decreasing the sensitivity of cells to many peptide and protein hormones. Other receptors, such as cytokine receptors, are also regulated by endocytosis and degradation.

16.2 The Ras/MAP Kinase Signal Transduction Pathway

Signal transduction by RTKs begins with the binding of a protein with an SH2 domain to a phosphorylated tyrosine of the receptor's cytosolic domain. After one or two additional steps that we will see shortly, virtually all receptor tyrosine kinases activate the *Ras/MAP kinase signal transduction pathway* (Figure 16-10; also see Figure 16-1a, Pathway A). This pathway is also activated by most cytokine receptors. It is conserved in evolution, as versions are found in vertebrates, invertebrates, and even in yeasts, and it plays a key role in many developmental pathways and regulates the growth and differentiation of many types of cells.

FIGURE 16-10 Activation of Ras following ligand binding to receptor tyrosine kinases (RTKs) or cytokine receptors. The receptor for fibroblast growth factor (FGF) exemplifies the activation of this signaling pathway. The SH2 domain of the cytosolic adapter protein GRB2 binds to a specific phosphotyrosine on an activated, ligand-bound receptor, and its SH3 domains bind to a cytosolic Sos protein, bringing it near the cytosolic surface of the plasma membrane and close to its substrate, the inactive Ras·GDP. The guanine nucleotide exchange factor (GEF) activity of Sos then promotes formation of active Ras·GTP from Ras·GDP. Note that Ras is tethered to the cytosolic surface of the plasma membrane by a hydrophobic farnesyl anchor (see Figure 10-19). See J. Schlessinger, 2000, *Cell* **103**:211; and M. A. Simon, 2000, *Cell* **103**:13.

The monomeric *Ras protein* belongs to the *GTPase superfamily* of intracellular switch proteins (see Figure 15-7). Activated Ras promotes the formation of a signal transduction complex, containing three sequentially acting protein kinases, at the cytosolic surface of the plasma membrane. This *kinase cascade* culminates in activation of certain members of the **MAP kinase** family, which can translocate into the nucleus and phosphorylate many different proteins. Among the target proteins for MAP kinase are transcription factors that regulate the expression of proteins with important roles in the cell cycle and in cell differentiation. Importantly, different hormones and their cell-surface receptors often differ in the strength or duration of the activation of a MAP kinase and thus in their effects on the cell. An activating mutation in an RTK, Ras, or a protein in the MAP kinase pathway that induces inappropriate cell division is found in almost all types of human tumors. Thus the RTK/Ras/MAP kinase signal transduction pathway has been studied extensively, and a great deal is known about its component proteins and their regulation (see Chapter 25).

We begin our discussion of the Ras/MAP kinase signal transduction pathway by reviewing how Ras cycles between the active GTP-bound and inactive GDP-bound states. We then describe how activated Ras passes a signal to the MAP kinase. Finally, we examine recent studies indicating that both yeasts and cells of higher eukaryotes contain multiple MAP kinase pathways, and we consider the ways in

which cells keep different MAP kinase pathways separate from one another through the use of scaffold proteins.

Ras, a GTPase Switch Protein, Operates Downstream of Most RTKs and Cytokine Receptors

Like the other G proteins, including the G_α subunits in trimeric G proteins that were discussed in Chapter 15, monomeric Ras proteins are G protein switches that alternate between an inactive "off" state with a bound GDP and a receptor-activated "on" state with a bound GTP (see Figure 15-7). Trimeric G proteins are activated upon binding directly to a ligand-bound GPCR that acts as a *guanine nucleotide exchange factor (GEF)* that triggers the release of the bound GDP. GTP then binds spontaneously to the nucleotide-free G protein. Activated RTKs and cytokine receptors are not GEFs; rather, the activated RTK or cytokine receptor recruits several adaptor proteins to the cytosolic surface of the plasma membrane, and one of these acts as the GEF that activates Ras.

Ras (~170 amino acids) is smaller than G_α proteins (~300 amino acids), but the GTP-binding domains of the two protein types have similar structures (see Figure 15-7 to review the structure of Ras). As with G_α proteins, hydrolysis of the bound GTP to GDP deactivates Ras. G_α proteins contain a GTPase-activating protein (GAP) domain

that increases the intrinsic rate of GTP hydrolysis, but this domain is not present in Ras. As a result, Ras has an intrinsically slower rate of GTP hydrolysis. Thus the average lifetime of a GTP bound to Ras is about 1 minute, much longer than the average lifetime of a G_α·GTP complex. Because of its low intrinsic GTPase activity, Ras·GTP requires the assistance of another protein, a GTPase-activating protein (GAP), to become deactivated. Binding of a GAP to Ras·GTP accelerates the intrinsic GTPase activity of Ras by more than a hundredfold; the actual hydrolysis of GTP to GDP and P_i is catalyzed by amino acids from both Ras and the GAP. The GAP for RAS (called a RAS-GAP) works by inserting one of its arginine side chains into the Ras active site, thus stabilizing an intermediate in the hydrolysis reaction.

As noted, mammalian Ras proteins have been studied in great detail because mutant Ras proteins are associated with many types of human cancer. These mutant proteins, which bind but cannot hydrolyze GTP, are permanently in the "on" state and contribute to the cellular transformation that leads to cancer (see Chapter 25). Determination of the three-dimensional structure of the Ras-GAP complex and tests of mutant forms of Ras explained the puzzling observation that most oncogenic, constitutively active Ras proteins (Ras^D) contain a mutation at position 12. Replacement of the normal glycine 12 with any other amino acid (except proline) blocks the functional binding of GAP proteins, vastly decreases the rate of

GTP hydrolysis, and in essence locks Ras in the active GTP-bound state. ■

The first indication that Ras functions downstream from RTKs in a common signaling pathway came from experiments on cultured fibroblast cells. These cells were induced to proliferate by treatment with a mixture of two protein hormones that activate RTKs: PDGF and EGF. Microinjection of anti-Ras antibodies into these cells blocked cell proliferation. Conversely, injection of Ras^{D}, a constitutively active mutant Ras protein, caused the cells to proliferate in the absence of the growth factors. These findings are consistent with studies using the pull-down assay method detailed in Figure 15-11 in which addition of FGF to fibroblasts led to a rapid increase in the proportion of Ras present in the GTP-bound active form.

Receptor Tyrosine Kinases Are Linked to Ras by Adapter Proteins

In order for activated RTKs and cytokine receptors to activate Ras, two cytosolic proteins — GRB2 and Sos — must first be recruited to provide a link between the receptor and Ras (see Figure 16-10). GRB2 is an *adapter protein*, meaning that it has no enzyme activity and serves as a link, or scaffold, between two other proteins — in this case, between the activated receptor and Sos. Sos is a GEF that

catalyzes conversion of inactive GDP-bound Ras to the active GTP-bound form. (The name *Sos* is an acronym for *Son of Sevenless*, a gene defined by analysis of *Drosophila* mutants with defects in eye development, which is critically dependent on a Ras-mediated signaling pathway.)

GRB2 is able to serve as an adapter protein because it has an SH2 domain, which binds to specific phosphotyrosine residues in the cytosolic domains of many activated RTKs. In addition to its SH2 domain, the GRB2 adapter protein contains two *SH3 domains*, which bind to Sos (see Figure 16-10). Like phosphotyrosine-binding SH2 domains, SH3 domains are present in a large number of proteins involved in intracellular signaling. Although the three-dimensional structures of various SH3 domains are similar, their amino acid sequences differ. The SH3 domains in GRB2 selectively bind to proline-rich sequences in Sos; different SH3 domains in other proteins bind to proline-rich target sequences distinct from those in Sos. Proline residues play two roles in the interaction between an SH3 domain in an adapter protein (e.g., GRB2) and a proline-rich sequence in its corresponding target protein (e.g., Sos). First, the proline-rich sequence assumes an extended conformation that permits extensive contacts with the SH3 domain, thereby facilitating interactions. Second, a subset of the prolines fit into binding pockets on the surface of the SH3 domain (Figure 16-11). Several nonproline residues also interact with the SH3 domain and are responsible for determining which SH3 domain binds to which target protein

(binding specificity). Hence the binding of proteins to SH3 and to SH2 domains follows a similar strategy: certain residues provide the key structural motif necessary for binding (phosphotyrosine for binding to SH2 domains, prolines for binding to SH3 domains), and neighboring residues confer specificity to the binding.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 16-11 Surface model of an SH3 domain bound to a target peptide. The short, proline-rich target peptide is shown as a stick model and the SH3 domain as a space-filling model. In this target peptide, two prolines (Pro4 and Pro7, dark blue) fit into binding pockets on the surface of the SH3 domain. Interactions involving an arginine (Arg1, red), two other prolines (gray), and other residues in the target peptide (green) determine the specificity of binding of the target peptide to an SH3 domain.

[Data from S. Feng et al., 1995, *Proc. Nat'l. Acad. Sci. USA* **92**:12408, PDB ID 1qwf.]

Binding of Sos to Inactive Ras Causes a Conformational Change That Triggers an Exchange of GTP for GDP

Following activation and autophosphorylation of an RTK (e.g., the FGF receptor) and binding of GRB2, Sos binds to GRB2, forming a complex on the cytosolic face of the plasma membrane (see Figure 16-10). The formation of this complex depends on the ability of GRB2 to bind simultaneously to the activated receptor and to Sos. Thus on receptor activation, Sos relocates from the cytosol to the membrane, bringing Sos close to its substrate, Ras·GDP, which is already bound to the cytosolic surface of the plasma membrane by means of a covalently attached lipid.

Binding of Sos to Ras·GDP activates Ras·GDP by releasing its GDP so that GTP can replace it. The binding of Sos leads to conformational changes in the switch I and switch II segments of Ras, thereby permitting GDP to diffuse away (Figure 16-12). In other words, Sos functions as a GEF for Ras. Binding of GTP to Ras, driven by the high GTP concentration in the cytosol relative to that of GDP, induces a specific conformation of switch I and switch II that allows Ras·GTP to activate Raf, the next protein in the Ras/MAP kinase pathway.

FIGURE 16-12 Structures of Ras bound to GDP, Sos protein, and GTP. (a) As with other G proteins bound to GDP, in Ras·GDP, the switch I (green) and switch II (blue) segments do not directly interact with GDP. (b) One α helix (yellow) in Sos binds to both switch segments of Ras·GDP, leading to a massive conformational change in Ras. In effect, Sos pries Ras open by displacing the switch I region, thereby allowing GDP to diffuse out. (c) GTP is thought to bind to the Ras-Sos complex first through its base (guanine); subsequent binding of the GTP phosphates completes the interaction. The resulting conformational change in the switch I and switch II segments of Ras, allowing both to bind to the GTP γ phosphate, displaces Sos and promotes interaction of Ras·GTP with its effectors (discussed later). The P loop (purple) is a sequence motif found in many ATP- and GTP-binding proteins that binds the β phosphate of the nucleotide. See Figure 15-7 for another depiction of Ras·GDP and Ras·GTP.

Signals Pass from Activated Ras to a Cascade of Protein Kinases Ending with MAP Kinase

Biochemical and genetic studies in yeast, *C. elegans, Drosophila*, and mammals have revealed that downstream of Ras is a highly

conserved cascade of three protein kinases, culminating in MAP kinase. Although activation of the kinase cascade does not yield the same biological results in all cells, all Ras/MAP kinase pathways have a common set of three sequentially acting kinases, as outlined in Figure 16-13: Ras → Raf → MEK → MAP kinase.

FIGURE 16-13 Ras/MAP kinase pathway. In unstimulated cells, most Ras is tethered to the cytosolic surface of the plasma membrane in the inactive form with bound GDP. Binding of a ligand to its RTK or cytokine receptor leads to formation of the active Ras·GTP complex (step 1; see also Figure 16-12). Activated Ras triggers the activation of the Raf kinase, activating the kinase cascade depicted in steps 2–6 and culminating in activation of MAP kinase (MAPK). In unstimulated cells, binding of a dimer of the 14-3-3 protein to Raf stabilizes its kinase domain in an inactive conformation. Each 14-3-3 monomer binds to a phosphoserine residue in Raf, one to phosphoserine-259 in the N-terminal domain and the other to phosphoserine-621 in the kinase domain; binding to 14-3-3 maintains the kinase in a closed, inactive state in the cytosol. Step 2: Binding of the Raf N-terminal regulatory domain to Ras·GTP results in dephosphorylation by a cytosolic enzyme of one of the serines that bind Raf to 14-3-3, leading to the consequent loss of 14-3-3 binding and partial activation of Raf

kinase activity. Maximum activation of Raf kinase activity occurs in part by formation of Raf dimers (not depicted), in which the kinase domain of one phosphorylates serine or threonine residues in the activation loop of the other. Step **3**: After the GTP bound to Ras is hydrolyzed to GDP, a process accelerated by a Ras-GAP, the inactive Ras·GDP dissociates from Raf. The Ras·GDP can be reactivated by signals from activated receptors, thereby recruiting additional Raf molecules to the membrane. As detailed in the text, in step **4** Raf phosphorylates and thus activates a MEK kinase, and in step **5** MEK phosphorylates and thus activates a MAP kinase. See E. Kerkhoff and U. Rapp, 2001, *Adv. Enzyme Regul.* **41**:261; J. Avruch et al., 2001, *Recent Prog. Horm. Res.* **56**:127; and D. Matallanas et al., 2011, *Genes Cancer* **2**:232.

In unstimulated cells, Raf is phosphorylated by several cytosolic kinases on two sites, one in its serine/threonine kinase domain and a second in its N-terminal autoinhibitory domain. These phosphate groups then bind to a dimer of the protein 14-3-3, which locks the autoinhibitory domain in a position where it blocks and inhibits the kinase active site — a *molecular handcuff*. Binding to 14-3-3 also retains the inactive Raf protein in the cytosol.

As noted, Ras is activated by the exchange of GDP for GTP (Figure 16-13, step **1**). Active Ras·GTP (but not Ras·GDP) binds to the N-terminal autoinhibitory domain of Raf, altering its conformation and allowing the phosphate attached to this domain to be removed by cytosolic phosphatases, thereby causing loss of 14-3-3 binding. This unblocks the kinase active site and partially activates its kinase activity (step **2**). Hydrolysis of Ras·GTP to Ras·GDP releases Raf from Ras (step **3**), and the released Raf then forms dimers in which the kinase activity of one phosphorylates serine or threonine

residues on the activation loop of the other, further increasing Raf kinase activity. In summary, binding of Ras·GTP to Raf, followed by hydrolysis of Ras·GTP to Ras·GDP, releases active Raf from its inhibitory complex with 14-3-3 (step **3**) and leads to activation of Raf kinase activity.

The now active Raf subsequently phosphorylates *MEK* on one or two serine residues in its activation loop, thereby activating MEK kinase activity (step **4**). MEK is a kinase that phosphorylates its target proteins on both tyrosine and serine/threonine residues; hence it is called a *dual-specificity* protein kinase. Active MEK mainly phosphorylates MAP kinase in its activation loop (step **5**). Active MAP kinase phosphorylates many different proteins, including nuclear transcription factors that mediate cellular responses that are discussed later (step **6**).

Several types of experiments have established the $\mathrm{Ras} \rightarrow \mathrm{Raf} \rightarrow \mathrm{MEK} \rightarrow \mathrm{MAP}$ kinase pathway. For example, cultured mammalian cells that express a mutant, nonfunctional Raf protein cannot be stimulated to proliferate uncontrollably by a constitutively active $\mathrm{Ras}^{\mathrm{D}}$ protein, one that has a permanently bound GTP. This finding established a link between the Raf and Ras proteins and showed that Raf lies downstream of Ras in the signaling pathway. In vitro binding studies further showed that the purified Ras·GTP protein binds directly to the N-terminal regulatory domain of Raf and activates its catalytic activity.

That MAP kinase is activated in response to Ras activation was demonstrated in quiescent (nondividing) cultured cells expressing a constitutively active Ras^D protein. In these cells, activated MAP kinase is generated in the absence of stimulation by growth-promoting hormones. Biochemical studies showed, however, that Raf cannot directly phosphorylate MAP kinase or otherwise stimulate its activity. The final link in the kinase cascade activated by Ras·GTP emerged from studies in which scientists fractionated extracts of cultured cells to search for a kinase activity that could phosphorylate MAP kinase and that was active only in cells stimulated with growth factors, not in unstimulated cells. This work led to the identification of MEK. Phosphorylation promotes not only the catalytic activity of MAP kinase, but also its dimerization. The dimeric form of MAP kinase is translocated to the nucleus, where it regulates the activity of many nuclear transcription factors. Later studies showed that MEK binds to the C-terminal catalytic domain of Raf and is phosphorylated on one or two serine residues in its activation loop by the Raf serine/threonine kinase (see Figure 16-13, step **4**); this phosphorylation activates the catalytic activity of MEK.

Given that the Ras/MAP kinase pathway is used in many cells and activated by many different receptors, it is not surprising that there are multiple isoforms of each of its components. In humans, there are three RAS, three Raf, two MEK, and two MAP proteins, and the isoforms have overlapping but also nonredundant functions.

Because Raf phosphorylates MEK, Raf and analogous MEK phosphorylating kinases in cells are often called *MEK kinases*, or *MEKK*. All eukaryotes including mammals possess multiple highly conserved Ras/MAP kinase pathways that are activated by different extracellular signals and that activate different MAP kinase proteins that phosphorylate different transcription factors; these transcription factors, in turn, trigger different changes in cell division, differentiation, or function. Mammalian MAP kinases include *Jun N-terminal kinases (JNKs)* and *p38 kinases*, which are activated by signaling pathways in response to various types of stresses and which phosphorylate various transcription factors and other types of signaling proteins that affect cell division.

Mutations in the *Raf* gene that lock its kinase domain in a permanently activated conformation occur in many types of tumors, in particular in about 50 percent of melanomas, skin cancers that are often caused by exposure to the ultraviolet radiation in sunlight. One such mutation, a glutamic acid substitution for the valine at position 600, occurs in over 90 percent of melanomas caused by exposure to UV radiation. This mutant constitutively active *Raf* kinase stimulates MAP-kinase signaling in cells in the absence of growth factors, promoting cell proliferation and preventing apoptosis (programmed cell death; see Chapter 22). Selective inhibitors of this mutant form of Raf have recently entered the clinic and generally produce short-term remission of the cancer. A combination of drugs that inhibit Raf and MEK appear more

promising and have recently entered clinical trials in patients with melanomas triggered by this mutant Raf. ■

MAP Kinase Regulates the Activity of Many Transcription Factors Controlling Early Response Genes

Addition of a growth factor such as EGF or PDGF to quiescent, nondividing cultured mammalian cells causes a rapid increase in the expression of as many as a hundred different genes. These genes are called *early response genes* because they are induced well before cells, in the G_0 or G_1 phase of the cell cycle, enter the S phase and replicate their DNA (see Chapter 19); many are turned on downstream of activated (phosphorylated and dimeric) MAP kinase (Figure 16-14). Consider the master transcription factor c-Fos. Together with other transcription factors, c-Fos induces the expression of many genes that encode proteins necessary for cells to progress through the cell cycle. The enhancer that regulates c-*fos* gene expression contains a *serum response element (SRE)*, so named because it is activated by many growth factors in serum. Activated MAP kinase induces transcription of the c-*fos* gene by directly phosphorylating and thus activating one transcription factor, *ternary complex factor (TCF)*. MAP kinase also phosphorylates and activates yet another kinase, termed $p90^{RSK}$, that in turn phosphorylates another transcription factor termed *serum response factor (SRF)*.

Association of phosphorylated TCF with two molecules of phosphorylated SRF forms an active transcription factor complex that activates c-*fos* gene transcription.

FIGURE 16-14 Induction of gene transcription by MAP kinase. Steps 1–3: In the cytosol, MAP kinase phosphorylates and activates the kinase $p90^{RSK}$, which then moves into the nucleus and phosphorylates a specific serine in the SRF transcription factor. Steps 4 and 5: After translocating into the nucleus, MAP kinase directly phosphorylates specific serines in the transcription factor TCF, which is already bound to the promoter of the c-*fos* gene. Step 6: Phosphorylated TCF and SRF act together to stimulate transcription of c-*fos* and other genes that contain an SRE sequence in their promoter. See the text for details. See R. Marais et al., 1993, *Cell* **73**:381; and V. M. Rivera et al., 1993, *Mol. Cell Biol.* **13**:6260.

Most RTKs that bind growth factors use the Ras/MAP kinase pathway to activate genes encoding proteins such as c-Fos, which in turn propel the cell through the cell cycle. Unlike the Raf and MEK kinases, which phosphorylate one or only a few target kinases in the Ras/MAP kinase cascade, MAP kinases are known to phosphorylate more than 200 proteins in the nucleus and cytosol. Many MAP kinase targets are regulators of gene expression, and different MAP kinase targets are expressed in different mammalian cell types. As with other transcription factors activated directly or indirectly by cell-surface receptors, the precise proteins induced by MAP kinase depend on the particular target proteins expressed in the cell, on epigenetic markers on DNA and chromatin proteins, and on the presence of other transcription factors (see Figure 16-2).

Multiple Feedback Mechanisms Restrain MAP Kinase Activation

Prolonged activation of the RTK–Ras/MAP kinase cascade may lead to inappropriate cell proliferation that would be deleterious to the organism. Accordingly, to maintain proper normal cell regulation, MAP kinase activation is tightly regulated through several feedback mechanisms. As with feedback control of other cellular pathways, these fall into two main categories: post-translational modification of pathway components and induction of synthesis of proteins that inhibit specific steps in the pathway. Inhibition of the Ras/MAP

kinase pathway by direct post-translational modification is nearly instantaneous, while many minutes are required to produce inhibitory protein(s) by de novo gene expression and protein synthesis and for these inhibitory proteins to influence their targets.

At the post-translational level, activated MAP kinase phosphorylates multiple proteins that act earlier in the pathway, reducing their ability to activate the MAP kinase pathway. For example, activated MAP kinase phosphorylates the HER1 EGF receptor on a threonine residue near the juxtamembrane domain (see Figure 16-8). Phosphorylation of this threonine residue decreases the ability of the receptor kinase to become fully active. Active MAP kinase also phosphorylates Raf on multiple sites, reducing its association with Ras and thus its ability to activate Ras. Such regulation effectively limits both the intensity and duration of MAP kinase activation.

Activation of the Ras/MAP kinase pathway also promotes increased transcription of regulators that lower the intensity and duration of MAP kinase signaling, a classic example of regulation by negative feedback. For example, activated MAP kinase triggers an increase in the expression of *du*al-*s*pecificity *p*hosphatases (DUSPs), particularly DUSP6. Their name is derived from their ability to dephosphorylate both the threonine and tyrosine phosphorylation sites in the MAP kinase activation loop, causing the loop to block the MAP kinase active site. DUSP6, along with several other negative regulators of the RTK–Ras/MAP kinase signaling cascade, are among the early

response genes whose transcription is increased rapidly — within the first 15 minutes — following MAP kinase activation. Increased expression of these phosphatases typically leads to transient inhibition of MAP kinase and can also suppress the response to a subsequent stimulation.

Scaffold Proteins Isolate Distinct MAP Kinase Pathways in the Same Cell from One Another

Two distinct signal transduction pathways within the same cell, initiated by two distinct receptors and having two distinct results, may share the identical protein kinase at some step. Yet this kinase will phosphorylate a different substrate depending on the pathway, even though both potential substrates are present in the cell. The principal mechanism that ensures that the correct substrate is phosphorylated is the formation of a complex by a scaffold protein. An example from yeast illustrates how the action of a scaffold protein guides the kinase to the correct substrate.

Yeast cells, like mammalian cells, utilize several MAP kinase pathways (Figure 16-15), but they are not activated by Ras-like proteins (which do not exist in yeasts). One pathway is activated by placing the cells in medium of high osmotic strength. The MAP kinase in this pathway, Hog1, phosphorylates transcription factors

that in turn activate genes whose proteins protect the cell against this osmotic challenge (Figure 16-15b). A second and distinct pathway is activated during mating of yeast cells of opposite mating type. Haploid yeast cells are either of the **a** or α mating type. An **a** haploid cell secretes the **a** mating factor and has cell-surface GPCRs that bind the α factor; an α cell secretes the α factor and has GPCRs that bind the **a** factor (see Figure 1-24). GPCRs that bind these factors initiate a MAP kinase pathway; the MAP kinase in this pathway, Fus3, translocates into the nucleus. There it phosphorylates and activates several transcription factors that turn on genes whose encoded proteins inhibit progression of the cell cycle and other genes that enable cells of opposite mating type to fuse together and ultimately form a diploid cell (Figure 16-15a).

FIGURE 16-15 Scaffold proteins separate yeast MAP kinase cascades in the mating and osmoregulatory pathways. In the budding yeast *Saccharomyces cerevisiae*, different cell-surface receptors activate different MAP kinase pathways, two of which are outlined here. (a) Mating pathway: The GPCR receptors for yeast α and **a** mating factors are coupled to the same trimeric G_α protein. Following ligand binding and dissociation of the G protein subunits, the released membrane-tethered $G_{\beta\gamma}$ subunit binds the Ste5 scaffold to the plasma membrane. $G_{\beta\gamma}$ then activates a signal transduction pathway (arrows) that culminates with the phosphorylation and thus activation of Ste11, which is analogous to Raf and other mammalian MEK kinase (MEKK) proteins. Ste11 initiates a MAP kinase cascade in which the final component, Fus3, is functionally equivalent to the MAP kinases (MAPK) in higher eukaryotes. Like other MAP kinases, activated Fus3 then translocates into the nucleus where it leads to phosphorylation and activation of several transcription factors — in this case ones that initiate transcription of genes that enable cells of opposite mating type to fuse together and ultimately form a diploid cell. (b) Osmoregulatory pathway: Two plasma membrane proteins, Sho1 and Msb1, are activated by exposure of yeast cells to media of high osmotic strength. Activated Sho1 recruits the Pbs2 scaffold protein, which contains a

MEK domain, to the plasma membrane, and activates a signal transduction pathway (arrows) that also results in phosphorylation and activation of Ste11. This initiates a different MAP kinase cascade that activates Hog1, a MAP kinase. After translocating to the nucleus, Hog1 phosphorylates several transcription factors and chromatin-modifying enzymes that induce transcription of genes that support survival in high-osmotic-strength media. Note that the MEK in this pathway is an integral domain of the Ste5 scaffold. See N. Dard and M. Peter, 2006, *BioEssays* **28**:146; and R. Chen and J. Thorner, 2007, *Biochim. Biophys. Acta* **1773**:1311.

There is a potential source of signaling confusion because, as Figure 16-15 shows, the same MEKK protein kinase, Ste11, is found in both pathways but phosphorylates different MEK kinases that are unique to each pathway. **Scaffold proteins** prevent Ste11 from phosphorylating the wrong MEK kinase. The scaffold protein Ste5, employed in the mating pathway, has no obvious catalytic function but stabilizes a large complex that includes the MEKK kinase Ste11, the MEK kinase Ste7, and the MAP kinase Fus3 in the mating signal transduction pathway. By binding to the $G_{\beta\gamma}$ protein that is released following activation of the mating factor GPCR, Ste5 ensures that the Ste11 bound to it is activated by the mating pathway. In contrast, the receptors that sense changes in extracellular osmotic strength, Sho1 and Msb2, cannot activate the MEKK Ste11 in the mating pathway complex.

Similarly, the Pbs2 scaffold protein is employed in the kinase cascade in the osmoregulatory pathway (see Figure 16-15) and binds to Sho1, an activator of the osmolarity pathway. This ensures that the Ste11 bound to it is activated only by the osmotic pathway; the

$G_{\beta\gamma}$ protein released following activation of the mating factor GPCR cannot activate the MEKK Ste11 in this osmo-sensing pathway complex.

Thus signaling downstream from Ste11 is restricted to the complex in which it is localized. As a result, exposure of yeast cells to mating factors induces activation of a single MAP kinase, Fus3, whereas exposure to a high osmolarity induces activation of a different MAP kinase, Hog1.

As emphasized in Figure 3-31, scaffolds also increase the rate of enzyme–catalyzed reactions by bringing the enzyme (e.g., a MEKK) close together to its substrate (a MEK), reducing the time needed for an enzyme to diffuse through an aqueous solution and find a substrate molecule.

Scaffolds for MAP kinase pathways are well documented in yeast, fly, worm, and mammalian cells. In addition to their ability to function as insulators for specific pathways, as described above for yeast Fus3 and Hog1, scaffold proteins can also regulate pathway activity. IQGAP1 is a mammalian scaffold protein that binds to RAF, MEK, and ERK kinases, as well as to a number of other proteins. Expression of IQGAP1 is increased in multiple different cancer types, and when its expression increases, so does the activity of the Ras–MAP kinase signaling cascade. Presumably IQGAP1 acts by bringing Raf, MEK, and ERK together into a single complex and thus facilitating their activation. Intriguingly, expressing in cells just the

domain of IQGAP that binds ERK is sufficient to inhibit the growth of melanoma cells that express a mutant, activated Raf protein. This small protein blocks the binding of ERK to the full-length IQGAP1 scaffold, thus preventing ERK's incorporation into the functional scaffold complex. This function of IQGAP suggests an alternate strategy for reducing MAP kinase activity in cancers. The signal specificity of the different MAP kinases in mammalian cells may arise from their association with different scaffold-like proteins, but much additional research is needed to test this possibility.

KEY CONCEPTS OF SECTION 16.2

The Ras/MAP Kinase Signal Transduction Pathway

- Ras is an intracellular GTPase switch protein that acts downstream from most RTKs and cytokine receptors. Like G_α, Ras cycles between an inactive GDP-bound form and an active GTP-bound form. Ras cycling requires the assistance of two proteins: a guanine nucleotide exchange factor (GEF) and a GTPase-activating protein (GAP).
- RTKs are linked indirectly to Ras via two proteins: GRB2, an adapter protein, and Sos, which has GEF activity (see Figure 16-10).
- The SH2 domain in GRB2 binds to a phosphotyrosine in activated RTKs, while its two SH3 domains bind Sos, thereby bringing Sos, a GEF, close to membrane-bound Ras·GDP and activating it.
- Binding of Sos to inactive Ras causes a large conformational change that permits release of GDP and binding of GTP, forming active Ras (see Figure 16-12).
- Activated Ras triggers a kinase cascade in which Raf (a MEK kinase or MEKK), MEK, and MAP kinase are sequentially phosphorylated and thus activated. Activated MAP kinase then translocates to the nucleus (see Figure 16-13).
- Activation of MAP kinase following stimulation of a growth-factor receptor leads to phosphorylation and activation of two transcription factors that promote transcription of various early response genes (see Figure 16-14).
- Different extracellular signals induce activation of different MAP kinase pathways, which regulate diverse cellular processes by phosphorylating different sets of

transcription factors.

- Multiple negative feedback mechanisms restrain MAP kinase activation — some depending on proteins whose gene transcription is induced by activated MEK.
- The kinase components of MAP kinase cascades can assemble into a large pathway-specific complex often stabilized by a scaffold protein (see Figure 16-15). This ensures that activation of one MAP kinase pathway by a particular extracellular signal does not lead to inappropriate activation of other pathways containing shared components.

16.3 Phosphoinositide Signal Transduction Pathways

In previous sections, we have seen how activated receptor tyrosine kinases (RTKs) initiate the Ras/MAP kinase pathway (see Figures 16-10 and 16-13). Here we discuss how these same receptors initiate some very different signaling pathways. These pathways have as intermediates certain phosphorylated phospholipids derived from phosphatidylinositol. As discussed in Chapter 15, these membrane-bound lipids are collectively referred to as **phosphoinositides**.

These signaling pathways include several enzymes that synthesize different phosphoinositides on the cytosolic face of the plasma membrane as well as cytosolic proteins with domains that can bind to these molecules. These proteins can thus be recruited to the cytosolic surface of the plasma membrane when the corresponding phosphoinositide is generated.

Several of these phosphoinositide pathways have long-term effects on patterns of gene expression as well as short-term effects. We will see that different phosphoinositide pathways end with activation of specific kinases, including protein kinase C (PKC) and protein kinase B (PKB), that play key roles in cell growth and metabolism. As an example, we will see in Chapter 21 how insulin activation of PKB plays a key role in rapidly stimulating glucose import into muscle and fat cells.

Phospholipase C_γ Is Activated by Many RTKs and Cytokine Receptors

In Chapter 15 we learned that hormonal stimulation of certain G protein–coupled receptors leads to the activation of phospholipase C (PLC). This membrane-associated enzyme then cleaves phosphatidylinositol 4,5-bisphosphate [$PI(4,5)P_2$] to generate two important second messengers: 1,2-diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). One of the resulting products, IP_3, triggers an increase in the concentration of Ca^{2+} in the cytosol with its many and diverse effects in different types of cells. A rise in the cytosolic Ca^{2+} level causes protein kinase C to translocate to the cytosolic surface of the plasma membrane, where it binds to DAG and becomes activated (see Figure 15-28); activation of PKC in different cells results in a varied array of cellular responses, indicating that it plays a key role in many aspects of cellular growth and metabolism.

As in the case for many signal transduction proteins, there are multiple isoforms of PLC. Via trimeric G proteins, GPCRs specifically activate the β isoform of this enzyme (PLC_β). Many RTKs (and the cytokine receptors discussed in the following section) activate a different isoform of phospholipase C, the γ isoform (PLC_γ), which contains an SH2 domain. This SH2 domain binds to specific phosphotyrosines on the cytosolic domains of these activated receptors, thus recruiting the PLC_γ enzyme from the cytosol to the cytosolic face of the plasma membrane, close to its

substrate, $PI(4,5)P_2$. In addition, the receptor phosphorylates tyrosine residues on the bound PLC_γ, enhancing its hydrolase activity. Thus activated RTKs and cytokine receptors promote PLC_γ activity in two ways: by localizing the enzyme to the membrane and by phosphorylating it. As detailed in Chapter 15, the IP_3/DAG pathway initiated by PLC has multiple physiological effects.

Recruitment of PI-3 Kinase to Activated Receptors Leads to Accumulation of Phosphatidylinositol-3-Phosphates in the Plasma Membrane and to Activation of Several Downstream Kinases

In addition to the IP_3/DAG pathway, many activated RTKs and cytokine receptors initiate another phosphoinositide pathway by recruiting the enzyme *phosphatidylinositol-3 kinase (PI-3 kinase)* to the cytosolic surface of the plasma membrane. PI-3 kinase is recruited to the plasma membrane by binding of its SH2 domain to phosphotyrosines on the cytosolic domain of many activated RTKs and cytokine receptors. This recruitment positions the catalytic domain of PI-3 kinase near its phosphoinositide substrates on the cytosolic face of the plasma membrane. Unlike kinases we have encountered earlier, which phosphorylate proteins, PI-3 kinase adds

a phosphate to the hydroxyl group on the 3′ carbon in one of two separate phosphatidylinositol substrates, leading to formation of either phosphatidylinositol 3,4-bisphosphate [$PI(3,4)P_2$] or phosphatidylinositol 3,4,5-trisphosphate [$PI(3,4,5)P_3$] — collectively called *PI 3-phosphates* (Figure 16-16). These membrane-bound PI 3-phosphate products of the PI-3 kinase act as docking sites for multiple signal-transducing proteins. Once bound to these phosphoinositides, these proteins transduce signals in several important pathways.

FIGURE 16-16 Generation of phosphatidylinositol 3-phosphates. The enzyme phosphatidylinositol-3 kinase (PI-3 kinase) is recruited to the cytosolic face of the plasma membrane by many activated receptor tyrosine kinases (RTKs) and cytokine receptors. The 3-phosphate added by this enzyme, to yield $\mathrm{PI(3,4)P_2}$ or $\mathrm{PI(3,4,5)P_3}$, is a binding site for various signal-transducing proteins, such as the PH domain of protein kinase B. See L. Rameh and L. C. Cantley, 1999, *J. Biol. Chem.* **274**:8347.

In some cells, this *PI-3 kinase pathway* triggers cell division and prevents apoptosis, thus ensuring cell survival. In other cells, this pathway induces specific changes in cell metabolism.

An important signal transduction protein that binds to PI 3-phosphates is **protein kinase B (PKB)**, a serine/threonine kinase that is also called **Akt**. In addition to its kinase domain, PKB contains a *PH domain*, a conserved protein domain present in a wide variety of signaling proteins that binds with high affinity to the 3-

phosphate in both $PI(3,4)P_2$ and $PI(3,4,5)P_3$. In unstimulated, resting cells, the concentration of these phosphoinositides is low; PKB is present in the cytosol in an inactive form because its PH domain physically blocks the kinase active site (Figure 16-17). Following ligand-induced receptor activation, the concentration of PI 3-phosphates rises. The PH domain of PKB binds to these PI 3-phosphates, so it no longer blocks the PKB kinase active site. PKB is thus recruited to the cytosolic face of the plasma membrane, and its unblocked kinase domain becomes partially activated. Maximal activation of PKB depends on recruitment to the cytosolic surface of the plasma membrane of two other kinases, named *PDK1* and *PDK2*.

FIGURE 16-17 Recruitment and activation of protein kinase B (PKB) in PI-3 kinase pathways. In unstimulated cells (step 1), PKB is in the cytosol with its PH domain bound to its catalytic kinase domain, inhibiting its activity. Hormone stimulation leads to activation of PI-3 kinase and subsequent formation of $PI(3,4)P_2$ or $PI(3,4,5)P_3$ (see Figure 16-16).

The 3-phosphate group on both serves as a docking site on the plasma membrane for the PH domain of PKB (step **2**) and another kinase, PDK1. Full activation of PKB requires phosphorylation both in the activation loop by PDK1 and at the C-terminus by a second kinase, PDK2, that is part of the mTORC2 complex described in Chapter 21 (step **3**). See A. Toker and A. Newton, 2000, *Cell* **103**:185; and S. Sarbassov et al., 2005, *Curr. Opin. Cell Biol.* **17**:596.

PDK1 is recruited to the plasma membrane via binding of its own PH domain to PI 3-phosphates. Anchored to distinct PI 3-phosphates, both PKB and PDK1 diffuse randomly in the plane of the plasma membrane, eventually coming close enough together so that PDK1 can phosphorylate PKB on a critical threonine residue in its activation loop — yet another example of kinase activation by phosphorylation. Phosphorylation by the mTORC2 kinase complex, described in Chapter 21, of a second serine on PKB that is not in the activation loop is necessary for maximal PKB activity (see Figure 16-17). As in the regulation of Raf activity (see Figure 16-13), release of an inhibitory domain and phosphorylation by other kinases regulate the activity of PKB.

Activated Protein Kinase B Induces Many Cellular Responses

Once fully activated, PKB can dissociate from the plasma membrane and phosphorylate its many target proteins throughout the cell. These targets have a wide range of effects on cell behavior. In many

cells, activated PKB directly phosphorylates and inactivates a protein termed *Bad*, which as its name suggests is not good for a cell's survival — it will induce programmed cell death (apoptosis; see Figure 22-42). Phosphorylation of Bad by PKB protects against apoptosis.

Activated PKB also promotes survival of many cultured cells by phosphorylating the Forkhead transcription factor FOXO3a on multiple serine and threonine residues. When FOXO3a is not phosphorylated, it mainly localizes to the nucleus, where it activates transcription of several genes encoding proteins that induce apoptosis. When growth factors are added to the cells, PI-3 kinase is activated, and consequently so is PKB. Activated PKB phosphorylates FOXO3a. The cytosolic phosphoserine-binding protein 14-3-3 then binds to phosphorylated FOXO3a and sequesters it in the cytosol. (Recall that many other phosphorylated proteins, including Raf, that bind to 14-3-3 are similarly retained in an inactive state in the cytosol; see Figure 16-13.) A FOXO3a mutant in which the three serine residues that are targets for PKB are mutated to alanines is constitutively active as a transcription factor and initiates apoptosis even in the presence of activated PKB. This finding demonstrates the importance of phosphorylation of FOXO3a by PKB in preventing induction of apoptosis.

Misregulation of PKB is implicated in the pathogenesis of both cancer and diabetes, and in Chapter 21 we will see how PKB,

activated downstream of the insulin RTK, promotes glucose uptake and storage in muscle and liver. This is another example of one signaling pathway controlling different cellular functions in different cells.

The PI-3 Kinase Pathway Is Negatively Regulated by PTEN Phosphatase

Like most intracellular signaling events, phosphorylation by PI-3 kinase is reversible. The phosphatase that removes the phosphates added by PI-3-kinase, termed *PTEN*, has an unusually broad specificity. Although PTEN can remove phosphate groups attached to serine, threonine, and tyrosine residues in proteins, its major function in cells is thought to be its ability to remove the 3-phosphate from $PI(3,4)P_2$ and $PI(3,4,5)P_3$ and thus suppress the PI-3 kinase signaling pathway. Overexpression of PTEN in cultured mammalian cells promotes apoptosis by reducing the level of $PI(3,4)P_2$ and $PI(3,4,5)P_3$, and hence reducing the activation of PKB and limiting its anti-apoptotic effect.

The *PTEN* gene is deleted in multiple types of advanced human cancers, and its loss contributes to the uncontrolled growth of cells. Indeed, cells lacking PTEN have elevated levels $PI(3,4,5)P_3$ and PKB activity. Because PKB inactivates a protein that induces apoptosis, loss of PTEN reduces the programmed cell death that is the normal

fate of many cells including many tumors. In certain cells, such as neuronal stem cells, absence of PTEN not only prevents apoptosis but also stimulates cell cycle progression and enhances the rate of cell proliferation. Knockout mice lacking PTEN have big brains with an excess number of neurons, attesting to PTEN's importance in the control of normal brain development. ■

KEY CONCEPTS OF SECTION 16.3

Phosphoinositide Signal Transduction Pathways

- Many RTKs and cytokine receptors initiate the $\mathrm{IP_3/DAG}$ signaling pathway by activating phospholipase $\mathrm{C_\gamma}$ $(\mathrm{PLC_\gamma})$, a different PLC isoform than the one activated by G protein–coupled receptors.
- Activated RTKs and cytokine receptors also can initiate another phosphoinositide pathway by binding a PI-3 kinase, thereby allowing the enzyme access to its membrane-bound phosphoinositide substrates, which then become phosphorylated at the 3 position (PI 3-phosphates $\mathrm{PI(3,4)P_2}$ and $\mathrm{PI(3,4,5)P_3}$; see Figure 16-16).
- The PH domains in various proteins bind to PI 3-phosphates, forming signaling complexes associated with the cytosolic face of the plasma membrane.
- Protein kinase B (PKB) becomes partially activated by binding with its PH domain to PI 3-phosphates. Full activation of PKB requires phosphorylation by the kinase PDK1, which is also recruited to the membrane by binding to PI 3-phosphates, and by a second kinase, PDK2 (see Figure 16-17).
- Activated PKB promotes survival of many cells by directly phosphorylating and inactivating several pro-apoptotic proteins and by phosphorylating and inactivating the FOXO3a transcription factor, which otherwise induces synthesis of pro-apoptotic proteins.
- Signaling via the PI-3 kinase pathway is terminated by the PTEN phosphatase, which hydrolyzes the 3-phosphate in PI 3-phosphates. Loss of PTEN, a common occurrence in human tumors, promotes cell survival and proliferation.

16.4 Cytokines, Cytokine Receptors, and the JAK/STAT Signaling Pathway

The **cytokines** form a family of relatively small, secreted signaling molecules, generally containing about 160–200 amino acids, that control growth and differentiation of many types of cells. All cytokines have a similar three-dimensional structure — four long, conserved α helices folded into a conserved three-dimensional structure. All cytokine receptors also have similar three-dimensional structures; they function similarly to RTKs and activate similar signal transduction pathways. Whereas in RTKs the protein tyrosine kinase is part of the receptor cytosolic domain, **cytokine receptors** and the kinase enzyme are separate polypeptides, encoded by different genes, yet are bound tightly together. The tightly bound kinase is known as a *JAK kinase*. (JAK is an acronym for "*J*ust *A*nother *K*inase" because when the first member of the family was cloned researchers knew it was a kinase from its sequence, but had no idea of its function.) In this section, we focus here on a pathway — the JAK/STAT pathway — mainly employed by cytokine receptors: the JAK kinase phosphorylates and activates a STAT transcription factor that moves directly to the nucleus. More specifically, the SH2 domain of a STAT transcription factor binds to a phosphotyrosine in the cytosolic domain of an activated cytokine receptor; the STAT transcription factor then becomes

phosphorylated by the JAK kinase, moves to the nucleus, and directly activates gene expression.

Cytokines Regulate the Development and Function of Many Cell Types

Growth hormone (GH), as its name implies, is a 191-amino-acid protein that stimulates proliferation of many types of body cells; it is made and secreted by cells in the anterior pituitary gland in response to another hormone, growth hormone–releasing hormone, that is made by the part of the brain termed the *hypothalamus*. GH was one of the first protein drugs to be made by recombinant DNA; it is used clinically to treat short stature caused by GH deficiency in children and adults. The bovine version is used to increase milk production in dairy cows. During pregnancy, a related hormone, the cytokine **prolactin**, induces epithelial cells lining the immature ductules of the mammary gland to differentiate into the acinar cells that produce milk proteins and secrete them into the ducts. GH and prolactin have three-dimensional structures very similar to those of the cytokines that induce the formation of important types of blood cells.

All blood cells are derived from hematopoietic stem cells, which form a series of progenitor cells that then differentiate into the mature blood cells (see Figure 22-18). For instance, the cytokine

granulocyte colony–stimulating factor (G-CSF) induces a granulocyte progenitor cell in the bone marrow to divide several times and then differentiate into granulocytes, a type of white blood cell that inactivates invading bacteria and other pathogens. A related cytokine, **thrombopoietin**, stimulates a different progenitor cell to divide and differentiate into megakaryocytes, huge cells that fragment into the platelets that are essential for blood clotting.

A structurally related cytokine, **erythropoietin (Epo)**, triggers production of erythrocytes (red blood cells) by inducing the proliferation and differentiation of erythroid progenitor cells in the bone marrow (Figure 16-18a). Erythropoietin is synthesized by certain kidney cells. The major function of erythrocytes is to transport oxygen complexed to hemoglobin. Thus a drop in blood oxygen, such as that caused by loss of blood from a large wound, signifies a lower than optimal level of red blood cells. As we learn in Chapter 21, the oxygen-sensing transcription factor HIF-1α becomes activated and induces the transcription of the erythropoietin gene; the kidney cells synthesize more of this cytokine and secrete it into the blood. As the level of erythropoietin rises, more and more erythroid progenitors are induced to divide and differentiate; each progenitor produces 30 to 50 erythrocytes in only a few days. In this way, the body can respond to the loss of blood or reduction in available atmospheric oxygen at high elevations by accelerating the production of erythrocytes. GH, prolactin, G-CSF, thrombopoietin, and Epo undoubtedly evolved from a common ancestral protein, since all of these cytokines have a similar tertiary structure.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 16-18 Erythropoietin and formation of red blood cells (erythrocytes). (a) Differentiation of erythroid progenitors to erythrocytes. Erythroid progenitor cells, called *colony-forming units–erythroid (CFU-E),* are derived from hematopoietic stem cells, which also give rise to progenitors of other blood cell types (see Figure 22-18). In the absence of erythropoietin, CFU-E cells undergo apoptosis (programmed cell death). Binding of Epo to its receptors on a CFU-E cell induces transcription of several genes whose encoded proteins prevent apoptosis, allowing the cell to survive. Other Epo-induced proteins trigger a developmental program of three to six terminal cell divisions, induction of hemoglobin and many other erythroid-important genes, reduction in cell and nuclear size, and finally, loss of the cell nucleus. If CFU-E cells are cultured with Epo in a semisolid medium (e.g., containing methylcellulose), daughter cells cannot move away, and thus each CFU-E cell produces a colony of 30–100 erythroid cells; hence its name. (b) Structure of erythropoietin bound to an erythropoietin receptor. Like other cytokines, erythropoietin (Epo) contains four conserved, long α helices that are folded into a conserved structural arrangement. The activated erythropoietin receptor (EpoR) is a dimer of identical subunits. Like the extracellular domains of all cytokine receptors, the extracellular domain of each monomer of the EpoR is constructed of two subdomains, each containing seven conserved β strands folded together in a characteristic and conserved structure. Side chains of residues on two of the α helices in Epo, termed *site 1*, contact loops on one EpoR monomer, while residues on the two other Epo α helices, termed *site 2*, bind to the same loop segments in a second receptor monomer, thereby stabilizing the dimeric receptor in a specific active conformation.

[Part (a) Data from M. Socolovsky et al., 2001, *Blood* **98**:3261. Part (b) Data from R. S. Syed et al., 1998, *Nature* **395**:511, PDB ID 1eer.]

Both Epo and G-CSF are produced commercially by recombinant expression in cultured mammalian cells. Patients with kidney disease, especially those undergoing dialysis, frequently are anemic (have a low red blood cell count) and therefore are treated

with recombinant Epo to boost red cell levels. Epo and G-CSF are used as adjuncts to certain cancer therapies because many cancer treatments reduce the production of red cells and granulocytes in the bone marrow. Epo can also be misused to increase red blood cell levels in endurance athletes (blood "doping"). ■

Cytokines include the *interferons*, which are produced and secreted by several cell types following viral infection. Interferons act on nearby cells to induce enzymes that render those cells more resistant to viral infection. Other cytokines, exemplified by Interleukin 2 (IL-2), mainly regulate cells of the immune system. IL-2 promotes the proliferation, differentiation, and survival of key cells of the immune system, including antibody-forming B cells and also several types of T cells (Chapter 24).

Binding of a Cytokine to Its Receptor Activates One or More Tightly Bound JAK Protein Tyrosine Kinases

GH, prolactin, G-CSF, thrombopoietin, and Epo all have similar structures, and they activate receptors of similar structure by forming dimers of two identical cytokine receptor proteins, a process termed *receptor homodimerization*. The extracellular domains of these cytokine receptors are constructed of two subdomains, each of which contains seven conserved β strands

folded together in a characteristic fashion (Figure 16-18b). Cytokines bind their receptors very tightly, as a consequence of molecular complementarity and multiple weak, noncovalent forces — that is, ionic, van der Waals, and hydrophobic interactions [see Figure 15-4; dissociation constants (K_d) of about 10^{-10} M]. Thus very low concentrations of GH and most other cytokines — about 1 microgram per liter (roughly one part in a billion) — are sufficient to activate cytokine receptors.

Other cytokines, including the interleukins and the interferons, bind simultaneously to two or more different cytokine receptors, a process called *receptor hetero-dimerization* or *hetero-oligomerization* (Figure 16-19b). IL-2 can bind first to the alpha chain (IL-2Rα), which does not directly interact with downstream signal transduction molecules, but rather enhances the binding of IL-2 to the two signaling subunits, the beta and gamma chains IL-2Rβ and IL-2Rγ. The same gamma chain is also an essential subunit of the receptors for several other interleukins, including IL-4, IL-7, IL-9, IL-15, and IL-21, cytokines that are essential for formation of B cells and other types of immune-system cells.

Severe combined immunodeficiency (SCID) is a genetic disease in which neither T nor B cells are produced. People with SCID cannot cope with any bacterial or viral infection, so they must be kept in a sterile environment (like the famous “bubble boy” who was kept in a plastic bubble and eventually succumbed to an infection).

Many cases of SCID are due to a deficiency in the IL-2 receptor gamma chain, whose gene is located on the X chromosome. These children can now be cured by gene therapy: a lentiviral vector (see Figure 6-37) is used to introduce a functional gamma chain gene into the hematopoietic stem cells that generate all immune-system cells (see Chapter 23), and the children can live normal lives. ■

The JAK family of kinases contain four members. An identical JAK kinase of one of these types is bound to the cytosolic domain of each of the two polypeptides in homodimeric receptors (Figure 16-19a, step **1**). Two distinct JAK kinase isoforms bind to heterodimeric receptors (Figure 16-19b). Despite this difference, the signaling pathways activated by all cytokine receptors are broadly similar; here we focus on the simpler case of receptors that homodimerize. Our example is the interaction of one erythropoietin molecule with two identical erythropoietin receptor (EpoR) proteins (Figures 16-19a and 16-20a).

FIGURE 16-19 Structure and activation of cytokine receptors. (a) Homodimeric receptors. The cytosolic domains of both cytokine receptor subunits bind tightly and irreversibly to the same JAK protein tyrosine kinase. In the absence of ligand (step 1), the receptors are largely monomers and the JAK kinases are poorly active. Ligand binding causes a conformational change in the receptors that brings together the JAK kinase domains, which

then phosphorylate each other on a tyrosine residue in the activation loop, activating kinase activity (step **2**). The active JAK kinases then phosphorylate multiple tyrosine residues in the receptor cytosolic domain (step **3**). As in RTKs (see Figure 16-1a), the resulting phosphotyrosines function as docking sites for SH2 domains of multiple signal-transducing proteins, including STAT proteins. (b) Heteromeric receptors, as exemplified by the binding of Interleukin 2 (IL-2) to the extracellular domains of the three subunits of the IL-2 receptor. Both the beta and gamma subunits of the IL-2 receptor (IL-2Rβ and IL-2Rγ) have structures similar to that of the Epo receptor. The alpha subunit (IL-2Rα) is expressed in some but not all responding cells and does not activate a signal transduction pathway. Its function is to bind IL-2 and facilitate the binding of IL-2 to the signaling IL-2Rβ and IL-2Rγ subunits. Each of the two signaling receptors, IL-2Rβ and IL-2Rγ, is bound to a different JAK kinase and activates different STAT signal-transducing proteins but otherwise the receptor complex activates similar same downstream signaling pathways as depicted in (a).

Each of the four members of the JAK family of kinases contains an N-terminal domain that binds to the receptor, a C-terminal kinase domain that has low catalytic activity when no ligand is bound, and a middle *pseudokinase* domain that regulates kinase activity by an as yet unknown mechanism. These kinases become activated after ligand binding and receptor dimerization (Figure 16-19a, step **1**); as with many RTKs, ligand binding triggers a conformational change in the JAKs such that they phosphorylate each other on a critical tyrosine in the activation loop (Figure 16-19a, step **2**; see Figure 15-6), which greatly enhances kinase activity. Also as with RTKs, the active JAK kinase phosphorylates several tyrosine residues in the receptor's cytosolic domain (Figure 16-19a, step **3**), creating binding sites for SH2 domains of many signal transduction proteins, including those that activate the Ras/MAP kinase and other signaling pathways discussed in Sections 16.2 and 16.3. Here we

focus on a pathway — the JAK/STAT pathway — mainly employed by cytokine receptors: the JAK kinase phosphorylates and activates a STAT transcription factor that moves directly to the nucleus (Figure 16-20a).

FIGURE 16-20 Activation and structure of STAT proteins. (a) Phosphorylation and dimerization of STAT proteins. Step **1**: Following dimerization and activation of a JAK kinase bound to a cytokine receptor (see Figure 16-19a), the SH2 domain of an inactive monomeric STAT transcription factor binds to a phosphotyrosine in the receptor cytosolic domain, bringing the STAT close to the active JAK associated with the receptor. The JAK then phosphorylates a specific C-terminal tyrosine in the STAT. Steps **2** and **3**: Phosphorylated STATs spontaneously dissociate from the receptor and spontaneously homodimerize. Because the STAT homodimer has two phosphotyrosine-SH2 domain interactions, whereas the receptor-STAT complex is stabilized by only one such interaction, phosphorylated dimeric STATs tend not to dissociate and rebind to the receptor. Step **4**: The STAT dimer moves into the nucleus, where it binds to promoter sequences and activates transcription of target genes. (b) Ribbon diagram of the STAT1 dimer bound to DNA (black). The STAT1 dimer forms a C-shaped clamp around DNA that is stabilized by reciprocal and highly specific interactions between the SH2 domain (purple) of one monomer and the phosphorylated tyrosine residue (yellow with red oxygens) on the C-terminal segment of the other. The phosphotyrosine-binding site of the SH2 domain in each monomer is coupled structurally to the DNA-binding domain (magenta), suggesting a potential role for the SH2-phosphotyrosine interaction in the stabilization of DNA interacting elements.

[Part (b) Data from X. Chen et al., 1998, *Cell* **93**:827, PDB ID 1bf5.]

JAK Kinases Phosphorylate and Activate STAT Transcription Factors

All STAT proteins contain an N-terminal DNA-binding domain, an SH2 domain, and a C-terminal domain with a critical tyrosine residue. Through its SH2 domain, a monomeric STAT binds to a specific phosphotyrosine in the cytosolic domain of an activated receptor (Figure 16-20a, step **1**). The C-terminal tyrosine then becomes phosphorylated by the adjacent JAK kinase (step **2**). This

arrangement ensures that in a particular cell, only those STAT proteins with an SH2 domain that can bind to a particular receptor will be activated when that receptor is activated by cytokine binding. For example, the erythropoietin receptor, as well as the receptors for GH, prolactin, G-CSF, and several other cytokines, activates STAT5, but not STATs 1, 2, 3, or 4. In contrast the IL-2 receptor complex activates STATs 1, 3, and 5 but not STATs 2 or 4 (see Figure 16-19b).

A phosphorylated STAT dissociates spontaneously from the receptor, and two phosphorylated STAT proteins form a homodimer in which the SH2 domain on each molecule in the dimer binds to the phosphotyrosine in the other molecule (Figure 16-20b). Conformational changes take place on dimerization that expose the nuclear-localization signal (NLS), which had been inaccessible in the unphosphorylated STAT. NLSs are present in virtually all transcription factors found in the cytosol and are required for their transport into the nucleus (see Chapter 13). Targeted by the NLS, the STAT dimers move into the nucleus, where they bind to specific **enhancers** or **promoters** (DNA regulatory sequences) controlling target genes and thus alter gene expression.

As noted above (see Figure 16-2), because different cell types have unique complements of transcription factors and unique epigenetic modifications of their chromatin, the genes that are available to be activated by any STAT are different in different cell types. For example, in mammary gland cells, STAT5 becomes activated following prolactin binding to the prolactin receptor and induces

transcription of genes encoding milk proteins. In contrast, when STAT5 becomes activated in erythroid progenitor cells following binding of Epo to the EpoR, it induces expression of the protein Bcl-x_L · Bcl-x_L prevents the apoptosis of these progenitors (see Chapter 22), allowing them to proliferate and differentiate into red blood cells. More generally, it is thought that in each type of cell, activated STAT proteins, like the other transcription factors discussed earlier, bind only to DNA sites in open chromatin and mainly to sites that have master transcription factors or other cell-specific gene regulatory proteins bound at adjacent sites. This strategy of activating sets of genes specific to specific cell types by a relatively limited set of receptors, JAK kinases, and STAT proteins, allows the control, via combinatorial diversity, of a vast array of cellular activities.

Multiple Mechanisms Suppress Signaling from Cytokine Receptors

In Chapter 15 and in this one, we saw several ways in which signaling from G protein–coupled receptors and RTKs is terminated to prevent cells from overresponding to external stimuli. Here we discuss two mechanisms by which cytokine receptor signaling is regulated.

Phosphotyrosine Phosphatases

Phosphotyrosine phosphatases are enzymes that remove (hydrolyze) phosphates from specific phosphotyrosines on specific target proteins. An excellent example of how phosphotyrosine phosphatase enzymes function to suppress the activity of protein tyrosine kinases is provided by SHP1, a phosphatase that negatively regulates signaling by several types of cytokine receptors. Its role was first identified by analysis of mutant mice (termed *motheaten*) that lacked this protein; they died because of excess production of several types of blood cells, including erythrocytes.

SHP1 dampens cytokine signaling by binding to a cytokine receptor and inactivating the associated JAK protein, as depicted in Figure 16-21a. In addition to a phosphatase catalytic domain, SHP1 has two SH2 domains. When cells are in the resting state, unstimulated by a cytokine, SHP1 is free in the cytosol and one of its SH2 domains physically binds to and masks the catalytic site in the enzyme's phosphatase domain. In the stimulated state, however, this blocking SH2 domain preferentially binds to a specific phosphotyrosine residue in the activated receptor and unblocks the catalytic site. The accompanying conformational change brings the SHP1 catalytic site adjacent to the phosphotyrosine residue in the activation loop of the JAK associated with the receptor. By removing this phosphate, SHP1 inactivates the JAK, so that it can no longer phosphorylate the receptor or other substrates including the STATs.

SOCS Proteins

In another example of negative feedback, among the genes whose transcription is induced by STAT proteins are those encoding a class of small proteins termed *s*uppressors *o*f *c*ytokine *s*ignaling (SOCS), which terminate signaling by cytokine receptors. All SOCS proteins contain an SH2 domain that binds to specific phosphotyrosines on an activated receptor (Figure 16-21b). Binding of SOCS to an activated receptor results in the degradation of both the receptor and its associated JAK kinase.

FIGURE 16-21 Two mechanisms for terminating cytokine signal transduction, as exemplified by the erythropoietin receptor (EpoR). (a) Short-term regulation: SHP1, a phosphotyrosine phosphatase, is present in an inactive form in the cytosol of unstimulated cells. Binding of an SH2 domain in SHP1 to a particular phosphotyrosine in the activated receptor unmasks its phosphatase catalytic site and positions it near the phosphorylated tyrosine in the activation loop region of JAK2. Removal of the phosphate from this tyrosine inactivates the JAK kinase. See S. Constantinescu et al., 1999, *Trends Endocrin. Met.* **10**:18. (b) Long-term regulation: SOCS proteins, whose expression is induced by the STAT5 protein in erythropoietin-stimulated erythroid progenitor cells, inhibit or permanently terminate signaling over longer periods. Binding of SOCS to specific phosphotyrosine residues on EpoR or JAK2 blocks binding of other signaling proteins (*left*). The SOCS box also targets the receptor as well as JAK2 for degradation by the ubiquitin-proteasome pathway (*right*). Similar mechanisms regulate signaling from other cytokine receptors. See B. T. Kile and W. S. Alexander, 2001, *Cell. Mol. Life Sci.* **58**:1627.

SOCS acts by targeting these two proteins to be degraded by a proteasome. SOCS proteins contain a domain, called the *SOCS box*, that recruits components of E3 ubiquitin ligases (see Figure 3-32) that polyubiquitinylate the receptor and the JAK kinase (a polymer of ubiquitins is covalently attached). The *polyubiquitin tail* marks the proteins for destruction by a proteasome (see Chapter 3), thereby permanently turning off JAK2-mediated signaling pathways until new receptors and JAK2 proteins can be made. The observation that proteasome inhibitors prolong JAK2 signal transduction supports this mechanism. One SOCS protein, SOCS-1, also binds to the critical phosphotyrosine in the activation loop of an activated JAK2 kinase, thereby inhibiting its catalytic activity.

Studies with cultured mammalian cells have shown that the cytokine receptor for growth hormone is suppressed by another SOCS protein, SOCS-2. Strikingly, mice deficient in SOCS-2 grow significantly larger than their wild-type counterparts; these mice have long bones and proportionate enlargement of most organs. Thus SOCS proteins play an essential, negative role in regulating intracellular signaling from the receptors for erythropoietin, growth hormone, and other cytokines.

KEY CONCEPTS OF SECTION 16.4

Cytokines, Cytokine Receptors, and the JAK/STAT Signaling Pathway

- Cytokines play numerous roles in development. Erythropoietin, a cytokine secreted by kidney cells, promotes proliferation and differentiation of erythroid progenitor cells in the bone marrow to increase the number of mature red cells in the blood (see Figure 16-18a).
- Cytokines such as GH, prolactin, Epo, and G-CSF have very similar tertiary structures, as do their receptors. These and related cytokines form a cytokine: receptor homodimer complex on the cell surface (see Figures 16-18b and 16-19a).
- Other cytokines, exemplified by Interleukin 2, interact with two or more different receptor subunits, forming cytokine: receptor heteromultimeric complexes (see Figure 16-19b).
- The cytosolic domains of cytokine receptors are tightly bound to a JAK protein tyrosine kinase, which becomes activated after cytokine binding and receptor dimerization or heteromerization and phosphorylates tyrosine residues on the cytosolic domain of the receptor (see Figure 16-19a).
- The JAK/STAT pathway operates downstream from all cytokine receptors and some RTKs. STAT monomers bound to phosphotyrosines on receptors are phosphorylated by receptor-associated JAKs, then dissociate from the receptor, dimerize and move to the nucleus, where they activate transcription (see Figure 16-20).
- Signaling from cytokine receptors is terminated by the phosphotyrosine phosphatase SHP1 and several SOCS proteins (see Figure 16-21).

16.5 The TGF-β Family of Growth Factors, Their Receptor Serine Kinases, and the Smad Transcription Factors They Activate

In this section, we discuss an evolutionarily conserved large family of signaling molecules, called the **transforming growth factor β (TGF-β)** family, as well as a conserved family of cell-surface receptors, called the *TGF-β receptor family*. Members of these two families are present in invertebrate organisms in phyla such as Porifera (sponges), and Cnidaria (coral and hydra) as well as in all vertebrates.

Kinase domains in TGF-β receptors phosphorylate and thus trigger the activation of a conserved class of transcription factors (the **Smads**) that regulate many growth and differentiation pathways. Like the STATs discussed in the previous section, Smads are located in the cytosol in unstimulated cells, but when phosphorylated they move into the nucleus to regulate transcription. As with cytokine signaling, the TGF-β pathways have widely diverse effects in different types of cells because different members of the TGF-β family activate different members of the TGF-β receptor family, which activate different members of the Smad group of transcription factors. In addition, as with other receptor-activated transcription factors, we will see that the same activated Smad

protein partners with different transcription factors and thus activates different sets of genes in different types of cells.

The mammalian TGF-β family contains 33 members and includes a number of related extracellular signaling molecules that play widespread roles in regulating development. The founding member of the TGF-β family, TGF-β1, was identified on the basis of its ability to induce a malignant phenotype in several cultured early-stage mammalian cancer cell lines (hence the name "transforming growth factor"); in this case, TGF-β1 promoted metastases, the spreading and invasion of primary tumors, as discussed in Chapter 25. Ironically, the principal function of all three human TGF-β isoforms, TGF-β1, 2, and 3, in most normal (non-cancerous) mammalian cells is to prevent their proliferation by inducing the synthesis of proteins, including $p15^{INK4B}$, which inhibit the cyclin-dependent kinases (CDKs) that are essential for progression into the DNA synthesis (S) phase of the cell cycle (see Figures 1-22 and 19-12).

TGF-β is secreted by many cells in the body and inhibits the growth of both the secreting cell (autocrine signaling) and neighboring cells (paracrine signaling). Loss of TGF-β receptors, or of any of several proteins in the TGF-β signal transduction pathway, releases cells from this growth inhibition and is seen frequently in the early development of human tumors. TGF-β proteins also promote expression of cell-adhesion molecules and extracellular-matrix

molecules, which play important roles in tissue organization (see Chapter 20).

Other members of the TGF-β family, *bone morphogenetic proteins (BMP)*, were initially identified by their ability to induce bone formation when implanted in mice. One of these, BMP2, is used clinically to strengthen bone after severe fractures. Of the numerous BMP proteins subsequently recognized, many induce key steps in development, including formation of mesoderm and the earliest blood-forming cells; some are important for maintaining the undifferentiated state of cultured embryonic and adult stem cells (see Chapter 22). Many have nothing to do with bones; for example, the BMP4/BMP7 heterodimer is important in dorsal-ventral (back-to-front) patterning in vertebrate embryos. Similarly, a *Drosophila* homolog of TGF-β, called *Dpp*, participates in dorsal-ventral patterning in fly embryos. In the early human male embryo another member of the human TGF-β family, Müllerian-inhibiting hormone (MIH), inhibits the development of the female reproductive tract, and thus is critical to sex differentiation at a specific time during the fetal development of human males.

TGF-β Proteins Are Stored in an Inactive Form in the Extracellular Matrix

In mammals, the monomeric active forms of all members of the TGF-β family contain a conserved cysteine residue that forms a disulfide bond linking two monomers into a dimer (Figure 16-22a), and the precursor proteins of all TGF-β family members dimerize in the endoplasmic reticulum immediately after synthesis. The genes for all members of the family encode a precursor polypeptide comprising a secretion signal peptide (Chapter 13), a ~250-residue prodomain, and the C-terminal ~110-residue TGF-β domain. The amino-terminal *prodomain* is required for proper folding and dimerization of the C-terminal TGF-β domain. As these dimeric precursor proteins pass through the Golgi complex, a protease severs the covalent connection between the prodomain and the TGF-β domain, but the prodomain and the mature TGF-β protein remain noncovalently attached.

FIGURE 16-22 Model for TGF-β latency and activation. (a) Ribbon diagram structure of a mature TGF-β homodimer. Three intrachain disulfide linkages (yellow) in each monomer stabilize a cystine-knot domain; another disulfide bond (red) links the two monomers. (b, c) TGF-β latency. TGF-β is synthesized with a 250-residue amino-terminal prodomain that in the Golgi is proteolytically cleaved from the mature growth factor but remains noncovalently attached even after secretion. Both the mature growth factor and the prodomain form homodimers. The prodomain, its "arm" and "straitjacket" segments remaining tightly wrapped around the TGF-β growth factor, prevents the latent TGF-β from binding to a cell-surface receptor. Disulfide bonds on the prodomain link it covalently to LTBP or to other proteins in the extracellular matrix (b), or to the GARP protein on the surface of the secreting cell (c), localizing the latent TGF-β near the cell that produced it. (d) TGF-β activation. Certain integrins, perhaps on the surface of a nearby cell, bind to the RGD motifs on the arm segment of the prodomain. Because these integrins are also linked to the rigid actin cytoskeleton on the cytosolic side of the plasma membrane (Chapter 20), movements of the cell exert a traction force against the RGD motif, pulling and elongating

the straitjacket segment of the prodomain. Consequently, the TGF-β dimer is released from the complex and is now able to bind to a cell-surface receptor and initiate signaling.

[Part (a) Data from S. Daopin et al., 1992, *Science* **257**:369, PDBID 2tgi. Parts (c, d) From A. Hinck et al., 2016, *Cold Spring Harb. Perspect. Biol.* **8**:a022103.]

After TGF-β is secreted from the cell, the presence of the prodomain prevents the mature TGF-β protein from binding to its cell-surface receptors; the TGF-β growth factor is thus said to be *latent*. In addition, the prodomain forms linkages that localize the latent TGF-β to the surface of the secreting cell, to a nearby cell, or to the extracellular matrix. Specifically, the side chain of a cysteine residue near the N-terminus of the prodomain becomes disulfide linked to one of several types of proteins in the extracellular matrix, such as *latent TGF-β binding protein* (*LTBP*; Figure 16-22b) or to a protein called *GARP* on the surface of the secreting cell (Figure 16-22c).

Several mechanisms can release the mature TGF-β dimer from the inhibitory prodomain, enabling the active TGF-β dimer to rapidly bind to nearby TGF-β receptors and initiate highly localized autocrine or paracrine signaling (Figure 16-22d). These mechanisms include cleavage of the prodomain by extracellular proteases and mechanical stress that pulls the prodomain away.

Mechanical stress may be generated by the binding of the prodomains to a protein on the surface of a moving cell. The prodomains of some TGF-β family members (e.g., TGF-β1 and TGF-β3) contain a three-amino-acid sequence motif, RGD (Arg-Gly-Asp),

that allows them to bind to certain members of the class of membrane proteins termed *integrins* on the surface of a nearby cell (discussed in Chapter 20); integrins bind to RGD motifs in many extracellular-matrix proteins. During cell migration, for example, a tensile force is generated due to movement of the cell containing the integrin relative to the extracellular matrix containing LTBP and the prodomain/TGF-β dimer. The force physically distorts the prodomain and frees the active TGF-β dimer, initiating TGF-β signaling.

Three Separate TGF-β Receptor Proteins Participate in Binding TGF-β and Activating Signal Transduction

The approach taken to identify the receptors for TGF-β1 is representative of typical biochemical approaches to identifying receptors (see Section 15.2). Investigators first labeled the purified TGF-β1 protein with the radioisotope iodine-125 (^{125}I; see Chapter 3) using conditions that covalently link ^{125}I to exposed tyrosine residues. The ^{125}I-labeled TGF-β1 (^{125}I-TGF-β1) was then incubated at 4 °C with cultured fibroblast cells that express the receptor. At 4 °C ligands bind to receptors, but endocytosis is inhibited. At the end of the incubation, unbound ^{125}I-TGF-β1 in the extracellular fluid was washed away and the cells with receptor-bound ^{125}I-TGF-β1 were treated with a chemical that covalently cross-links proteins that are

physically close to one another, including ligands bound to their receptors. The cells were then disrupted and the investigators purified any proteins (and cross-linked protein complexes) that were radioactively labeled. Analysis of the purified proteins showed that ^{125}I-TGF-β1 was cross-linked primarily to three different polypeptides with molecular weights of 55, 85, and 280 kDa, referred to as *TGF-β receptors RI*, *RII*, and *RIII*, respectively.

Many additional experiments established that RI and RII are each homodimeric proteins; each polypeptide chain has both a single transmembrane segment and a serine/threonine kinase as part of its cytosolic domain. RI and RII together are sufficient to serve as a functional heterotetrameric TGF-β receptor. RIII is a transmembrane cell-surface protein expressed in some but not all cell types. Because RIII contains large, covalently bound oligosaccharide chains, it is a member of the class of glyco (sugar containing) proteins called *proteoglycans* (see Figure 20-33). The function of RIII for TGF-β receptors is similar to that of the α subunit of the IL-2 receptor described above (Figure 16-19b); RIII binds and concentrates TGF-β molecules near the cell surface, facilitating their subsequent binding to the signaling receptors RII and RI (Figure 16-23, step **1a**). As most cells lack RIII, TGF-β binds directly to the RII dimer (Figure 16-23, step **1b**). This step takes place before the RII dimer and RI bind each other (Figure 16-23, step **2**). The complex is inactive until RI binds.

FIGURE 16-23 Activation of the TGF-β receptor kinases. Step **1a**: In cells that express the type III TGF-β receptor (RIII), TGF-β binds first to this receptor, which concentrates TGF-β near the cell surface and thus facilitates the binding of TGF-β to one of the two type II TGF-β signaling receptors (RII) in a homodimeric complex. Step **1b**: In most cells, RIII is not expressed and TGF-β binds directly to one molecule of RII, a constitutively active kinase. Step **2**: Ligand-bound RII recruits a type I TGF-β receptor (RI), such that one monomer of the TGF-β dimer binds simultaneously to one RII and one RI protein. The constitutively active RII protein kinase then phosphorylates serine and threonine residues in the juxtamembrane segment of the RI receptor, releasing the inhibition of RI kinase activity. The now active type I receptor kinase then phosphorylates a Smad transcription factor.

In the tyrosine kinase and cytokine receptors we have already discussed, ligand binding induces a substantial increase in kinase activity, which is required for activating intracellular signal transduction pathways. In contrast, the dimeric RII subunits of the TGF-β receptor exhibit *constitutive* kinase activity; that is, their kinase domains are enzymatically active even when there is no TGF-

β bound. Active RII kinase activity is not sufficient to generate an intracellular signal. However, the binding of TGF-β to RII generates a new molecular surface at the TGF-β–RII interface that binds to a dimeric RI receptor (Figure 16-23, step **2**), generating a complex that contains one dimeric TGF-β molecule and one each of the RI and RII receptor homodimers — another example of ligand-induced receptor hetero-oligomerization. RI will not bind to RII unless RII is bound to TGF-β. An RII subunit in the complex then phosphorylates serine and threonine residues in a highly conserved sequence of the attached RI subunit adjacent to the cytosolic face of the plasma membrane, thereby activating RI kinase activity. The RI kinase then sets in motion the downstream intracellular signaling pathway.

Activated RI TGF-β Receptors Phosphorylate Smad Transcription Factors

The transcription factors downstream of the TGF-β receptors are called *Smads*. Three types of Smad proteins function in the TGF-β signaling pathway: *R-Smads* (receptor-regulated Smads; Smad2 and Smad3), *co-Smads* (Smad4), and *I-Smads* (inhibitory Smads; Smad7). Smad2 and/or Smad3 become phosphorylated by active RI receptors and together with Smad4 move into the nucleus to activate gene transcription; in contrast, I-Smads block the TGF-β signaling pathway, as discussed at the end of this section.

As illustrated in Figure 16-24a, all R-Smads share a similar domain architecture comprising an N-terminal MH1 domain, a central proline-rich linker, and a C-terminal MH2 domain. The MH1 domain contains a DNA-binding segment as well as a *nuclear-localization signal (NLS)*. However, when R-Smads are in their inactive, nonphosphorylated state, the NLS is masked so that it cannot direct the Smad into the nucleus (see Figure 13-35), and the MH1 and MH2 domains associate in such a way that they could not bind to DNA or to a co-Smad. Phosphorylation of two serine residues in a common Ser-X-Ser motif at the extreme C-terminus of the MH2 domain by the activated RI subunits of the TGF-β receptor separates the two domains, exposing the NLS for binding to importins and nuclear import (see Figure 13-36). Simultaneously, the two serines in each Smad2 or Smad3 that were phosphorylated by the TGF-β RI receptor kinase bind to phosphoserine-binding sites in the MH2 domains of a Smad4 or Smad2/3 protein, forming a stable complex containing two molecules of phosphorylated Smad3 (or Smad2) and one molecule of the co-Smad (Smad4). (Smad4 does not get phosphorylated but is essential to form a functional heterotrimeric Smad complex.) The bound importin then mediates translocation of the R-Smad/co-Smad complex into the nucleus. After importin dissociates inside the nucleus, the Smad3/Smad4 (or Smad2/Smad4) complex binds to other transcription factors to activate transcription of specific target genes, for example, the protease inhibitor gene PAI-1 in Figure 16-24a.

FIGURE 16-24 Activation of the TGF-β/Smad signaling pathway and its inhibition. (a) Activation. Step **1**: The activated type RI receptor kinase (see Figure 16-23) phosphorylates Smad2 or Smad3 (shown here as Smad2/3), causing a conformational change that unmasks its nuclear-localization signal (NLS). Step **2**: Two phosphorylated molecules of Smad2/3 bind to one co-Smad (Smad4) molecule, which is not phosphorylated, and to an importin, forming a multiprotein cytosolic complex. Steps **3** and **4**: After the entire complex translocates into the nucleus, Ran·GTP causes dissociation of the importin, as discussed in Chapter 13. Step **5**: One or more nuclear transcription factors (e.g., TFE3) then associates with the Smad2/3/Smad4 complex, forming an activation complex that cooperatively binds to a regulatory sequence of a target gene. Step **6**: This complex then recruits transcriptional co-activators and induces gene transcription (see Chapter 8). Smad2/3 is eventually dephosphorylated by a nuclear phosphatase (step **7**) and escorted by an exportin (not shown) returns to the cytosol through a nuclear pore (step **8**), where it can

be reactivated by another TGF-β receptor complex. Shown is the activation complex for the gene encoding plasminogen activator inhibitor (PAI-1); similar transcription complexes activate expression of genes encoding other extracellular-matrix proteins such as fibronectin. (b) Ski-mediated inhibition of transcription mediated by the Smad complex. Ski, whose synthesis is induced by the Smad2/3/Smad4 complex formed after TGF-β addition, represses Smad function by binding directly to Smad4. Since the Ski-binding domain on Smad4 significantly overlaps with the Smad4 MH2 domain required for binding the phosphorylated C-terminus of Smad3, binding of Ski disrupts the normal interactions between Smad3 and Smad4 necessary for transcriptional activation. In addition, Ski recruits the protein N-CoR, which binds directly to mSin3A; in turn, mSin3A interacts with a histone deacetylase (HDAC), an enzyme that promotes histone deacetylation on nearby promoters and enhancers, repressing gene expression (see Chapter 8). As a result of both processes, transcription activation induced by TGF-β and mediated by Smad complexes is shut down. The related protein SnoN functions similarly to Ski in repressing TGF-β signaling.

[Part (a) Data from S. Daopin et al., 1992, *Science* **257**:369, PDB ID 2tgi; A. Moustakas and C.-H. Heldin, 2009, *Development* **136**:3699; and D. Clarke and X. Liu, 2008, *Trends Cell Biol*. **18**:430. Part (b) Data from J. Deheuninck and K. Luo, 2009, *Cell Res.* **19**:47.]

An R-Smad's time in the nucleus is limited to prevent overstimulation of the cell. Within the nucleus, R-Smads are further modified by phosphorylation of their linker domains, acetylation of their MH1 domains, and dephosphorylation of the C-terminal serines by nuclear phosphatases. Collectively, these many modifications result in diminution of transcriptional activity and ultimately in dissociation of the R-Smad/co-Smad complex and export of the Smads from the nucleus *via* exportin proteins. Thus the concentration of active Smads within the nucleus closely reflects the levels of activated TGF-β receptors on the cell surface, allowing the regulation of gene transcription to closely follow the level of active TGF-β in the environment.

BMP proteins, which also belong to the TGF-β family, bind to and activate a different set of receptors that are similar to the TGF-β RI and RII proteins but phosphorylate other R-Smads, Smad1, Smad5, and Smad8. Two of these phosphorylated Smads then form a trimeric complex with Smad4, and this Smad complex activates different transcriptional responses from those induced by the TGF-β receptors.

The R-Smad/co-Smad Complex Activates Expression of Different Genes in Different Cell Types

Virtually all mammalian cells secrete at least one TGF-β isoform, and most have TGF-β receptors on their surface. However, the cellular responses induced by TGF-β vary among cell types, depending on the transcription factors that can partner with the R-Smad/co-Smad complex. In epithelial cells and fibroblasts, for example, TGF-β induces expression of extracellular-matrix proteins (e.g., fibronectins and collagens; see Chapter 20); it also induces expression of proteins that inhibit serum proteases, which otherwise would degrade these extracellular-matrix proteins. The inhibition of serum proteases stabilizes the matrix, allowing cells to form stable tissues. In many cells the R-Smad/co-Smad complex promotes expression of genes encoding other proteins such as $p15^{INK4B}$, which arrests the cell cycle at the G_1 stage and thus blocks

cell proliferation (see Chapter 19). More generally, binding of the R-Smad/co-Smad complex to DNA requires other transcription factors to bind at adjacent sites in the DNA; often these transcription factors are master transcription factors that determine the identity of a cell during its development. Equally important, in order for the R-Smad/co-Smad complex to bind to a DNA regulatory region and activate a given gene, the DNA binding segment must be in an active "open" chromatin conformation (see Figure 16-2).

Loss of TGF-β signaling plays a key role in the early development of many cancers. Many human tumors contain inactivating mutations in either TGF-β receptors or Smad proteins and thus are resistant to growth inhibition by TGF-β (see Figure 25-18). Most human pancreatic cancers, for instance, contain a deletion in the gene encoding Smad4 and thus cannot induce cell-cycle inhibitors such as $p15^{INK4B}$ in response to TGF-β. In fact, Smad4 was originally called *DPC* (*d*eleted in *p*ancreatic *c*ancer). Retinoblastoma, colon and gastric cancer, hepatomas, and some T- and B-cell malignancies are also unresponsive to TGF-β growth inhibition. This loss of responsiveness correlates with loss of RI or RII; responsiveness to TGF-β can be experimentally restored by recombinant expression of the "missing" protein. Loss-of-function mutations in Smad2 also commonly occur in several types of human tumors. ■

Negative Feedback Loops Restrain TGF-β/Smad Signaling

As discussed previously in the context of other signaling pathways, the response to most growth factors and other signaling molecules decreases with time, a phenomenon called *desensitization*. This response is adaptive because it prevents overreaction and makes fine-tuned control of cellular responses possible. Two cytosolic proteins called *SnoN* and *Ski* (*Ski* stands for "*S*loan-*K*ettering Cancer *I*nstitute") are induced by TGF-β signaling in virtually all body cells and serve to suppress the TGF-β/Smad signaling pathway. These proteins were originally identified as cancer-causing *oncoproteins* because their expression is elevated in many cancers, including melanomas and certain breast cancers; consequently, growth-inhibitory proteins normally induced by the TGF-β signal transduction pathway are not produced. Indeed, when overexpressed in cultured primary fibroblast cells, Ski or SnoN can cause abnormal cell proliferation, and suppression of Ski in pancreatic cancers reduces tumor growth.

SnoN and Ski trigger abnormal cell proliferation by binding to both the co-Smad (Smad4) and phosphorylated R-Smads (Smad3) after stimulation by TGF-β. SnoN and Ski do not prevent an R-Smad/co-Smad complex from forming or a Smad complex from binding to DNA regulatory regions. Rather, they block a Smad complex bound to DNA from activating transcription, in part by inducing

deacetylation of histones in adjacent chromatin segments. With Smad blocked from activating transcription, the growth-inhibitory effects of TGF-β are diminished (Figure 16-24b). The increased levels of SnoN and Ski proteins induced by TGF-β are thought to dampen the long-term effects of signaling due to continued exposure to TGF-β; this is another example of negative feedback, in which a gene induced by TGF-β signaling, in this case *SnoN*, inhibits further signaling by TGF-β.

Among other proteins induced after TGF-β stimulation are the I-Smads, especially Smad7. Smad7 binds to the activated RI subunit of TGF-β receptors and blocks its ability to phosphorylate Smad2 or Smad3. Like SOCS proteins in the cytokine signaling pathway (see Figure 16-21), Smad7 also recruits an E3 ubiquitin ligase that targets TGF-β receptors for degradation. In these ways, Smad7, like Ski and SnoN, participates in a negative feedback loop: its induction inhibits intracellular signaling stimulated by long-term exposure to the stimulating TGF-β hormone.

KEY CONCEPTS OF SECTION 16.5

The TGF-β Family of Growth Factors, Their Receptor Serine Kinases, and the Smad Transcription Factors They Activate

- The transforming growth factor β (TGF-β) family includes a number of related extracellular signaling molecules that play widespread roles in regulating development.
- TGF-β dimers are stored in an inactive form bound to the inhibitory prodomain on a cell surface or in the extracellular matrix; release of active dimers — by mechanical

stretching or protease digestion of the prodomain — initiates TGF-β signaling (see Figure 16-22).

- TGF-β receptors consist of three types of subunits (RI, RII, RIII). Binding of members of the TGF-β family to the RII subunit, a constitutively active kinase, allows recruitment of the RI subunit to the RII subunit. RII phosphorylates the cytosolic domain of the RI subunit, activating RI's serine/threonine kinase domain. RI then phosphorylates an R-Smad, exposing a nuclear-localization signal (see Figures 16-23 and 16-24).
- After phosphorylated R-Smads bind a co-Smad, the resulting complex translocates into the nucleus, where it interacts with various transcription factors to induce expression of target genes (see Figure 16-24).
- The Smad3/Smad4 complex often induces different genes in different cells by binding to regulatory DNA sequences at sites adjacent to those occupied by cell-specific master transcription factors (see Figure 16-24a).
- TGF-β signaling generally inhibits cell proliferation. Loss of any of several components of this signaling pathway can contribute to abnormal cell proliferation and malignancy.
- Oncoproteins (e.g., Ski and SnoN) and I-Smads (e.g., Smad7) suppress the TGF-β signaling pathway by inhibiting transcription mediated by the Smad2/3/Smad4 complex (see Figure 16-24b).

16.6 Signal Transduction Pathways That Utilize Regulated, Site-Specific Protein Cleavage: Notch/Delta and EGF Precursors

All of the signaling pathways we have discussed so far are reversible and so can be suppressed or turned off relatively quickly if the extracellular signal is removed. In this section and the next, we discuss several pathways that are irreversible or only slowly reversible. Many of these pathways trigger key steps in metazoan differentiation, and the irreversibility of a signal transduction pathway can lock the cell into undergoing a specific series of developmental events. In these pathways, a critical protein — a receptor, a transcription factor, or a protein in a signaling cascade that regulates a transcription factor — undergoes regulated cleavage.

On Binding Delta, the Notch Receptor Is Cleaved, Releasing a Component Transcription Factor

We begin by looking at a pathway in which cleavage of a protein releases a domain that affects the transcription of multiple target genes. In the Notch/Delta pathway (Figure 16-25a), the signaling molecule is Delta, an integral membrane protein bound to the

surface of the signaling cell. Delta binds to the extracellular domain of the receptor, Notch, on a neighboring responding cell. The binding of Delta triggers two sequential proteolytic cleavages of Notch, releasing the Notch intracellular domain. That cleavage product then moves into the nucleus and functions as a transcriptional activator.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 16-25 Notch/Delta signaling pathway. (a) In the absence of Delta, the transmembrane subunit of Notch on the surface of a responding cell is noncovalently

associated with its extracellular subunit; the extracellular domain is folded so that it cannot be cleaved by the cell-surface matrix metalloprotease ADAM 10. Binding of Notch to its ligand Delta on an adjacent signaling cell (step **1**) is followed by endocytosis of Delta by the signaling cell (step **2**), stretching the Notch extracellular domain so that ADAM 10 is able to cleave it (step **3**). The released fragment of the Notch extracellular domain remains bound to Delta and is endocytosed by the signaling cell and degraded in lysosomes (step **4**). Next the four-protein γ-secretase complex binds to the stump generated by ADAM 10 (step **5**), and then the protease in the complex, presenilin 1, catalyzes cleavage of the Notch transmembrane alpha helix near the cytosolic face of the membrane, releasing the cytosolic segment of Notch (step **6**). Following translocation to the nucleus, this Notch segment does not directly bind to DNA but rather interacts with several transcription factors to affect expression of genes that in turn influence the determination of cell fate during development (step **7**). See R. Kovall et al., 2017, *Dev. Cell* **41**:228; and S. Bray, 2016, *Nat. Rev. Mol. Cell Biol.* **17**:772. (b) High resolution structure of the four-protein γ-secretase complex determined by cryoelectron microscopy. A bound Notch transmembrane peptide that contains the intermembrane cleavage site is colored red and the presenilin (PS1) subunit is colored cyan. The protease catalytic site in PS1 is located near the cytosolic surface.

[Part (b) Data from G. Yang et al., 2019, *Nature* **565**:192.]

Both Notch and Delta are cell-surface, single membrane-spanning proteins. Notch also has other ligands, but the molecular mechanisms of Notch activation are the same with each. Notch is synthesized as a monomeric membrane protein in the endoplasmic reticulum. In the Golgi complex, it undergoes a proteolytic cleavage that generates an extracellular subunit and a transmembrane subunit that remain noncovalently associated with each other on the cell surface.

The first of two cleavages of the Notch extracellular domain is performed by ADAM 10, a *metalloprotease* and member of a class of metal-containing enzymes localized to the plasma membrane that cleave the extracellular segments of target proteins at a site near the plasma membrane. ADAM is an abbreviation for *a d*isintegrin *a*nd *m*etalloprotease; a *disintegrin* is a conserved protein domain that binds integrins and disrupts cell-matrix interactions (see Chapter 20). ADAM 10 cannot cleave Notch in the absence of Delta on an adjacent cell, because then the Notch extracellular domain is folded such that ADAM 10 cannot access the protease cleavage site (see Figure 16-25a).

After Delta binds to Notch (Figure 16-25a, step **1**), the Delta in the signaling cell undergoes endocytosis (step **2**). The force accompanying the movement of Delta into the signaling cell stretches the Notch protein on the responding cell, changing its conformation and allowing access by ADAM 10, which cleaves the Notch extracellular domain (step **3**). The Notch extracellular domain remains bound to Delta, is internalized by the signaling cell, and is probably degraded in lysosomes (step **4**).

A second cleavage of Notch follows quickly but this time it occurs within the hydrophobic membrane-spanning region of Notch; it is catalyzed by a transmembrane complex termed *γ-secretase* that contains *presenilin 1* (PS1), the protease enzyme, and three other essential subunits (Figure 16-25a, step **5**, and Figure 16-25b).

Cleavage by the *γ-secretase* complex releases the Notch cytosolic segment, which immediately translocates to the nucleus (Figure 16-25a, step **6**). This Notch intracellular domain does not bind directly to DNA. Rather it interacts with a single DNA-binding transcription factor, CSL (RBPJ in vertebrates) whereby it affects transcription of different target genes depending on the cell type. Its effect, like those of other transcription factors activated downstream of other cell-surface receptors, depends on the constellation of epigenetic chromatin marks and the presence of cell-specific transcription factors; it can both increase and decrease gene expression.

Metalloproteases Catalyze Cleavage of Many Signaling Proteins from the Cell Surface

We next look at a pathway in which the cleavage of a cell surface protein releases a signaling molecule rather than a transcription factor. Many growth factors and other signaling molecules are synthesized as transmembrane proteins whose signal domain extends into the extracellular space. Some such proteins, like Delta described above, are often biologically active but can signal only by binding to receptors on adjacent cells. In other cases, proteolytic cleavage of such proteins can release the soluble, active signaling molecule into the extracellular space; from there the signaling molecule can bind to receptors on nearby cells. The cleavage

producing these signaling molecules is often carried out by ADAMs. The human genome encodes 21 metalloproteases in the ADAM family, but only 12 are known to be catalytically active; many are involved in cleaving the transmembrane precursors of signaling proteins just outside their transmembrane segment, releasing the soluble signaling protein into the extracellular space.

Medically important examples of signaling proteins released from the cleavage of precursors are members of the EGF family, including EGF, HB-EGF, TGF-α, NRG1, and NRG2 discussed earlier (see Figures 16-6 and 16-7), which affect the proliferation and differentiation of many types of body cells. The activity of one or more ADAMs is increased in many cancers, leading to high levels of extracellular EGF-family growth factors. These stimulate the secreting cells (autocrine signaling) or adjacent cells (paracrine signaling) to proliferate inappropriately.

ADAM proteases also are an important factor in heart disease. As we learned in the last chapter, stimulation of β-adrenergic receptors in heart muscle by epinephrine (adrenaline) causes glycogenolysis and an increase in the rate of muscle contraction. Prolonged treatment of heart muscle cells with epinephrine, however, leads to activation of an ADAM by an unknown mechanism. This ADAM protease cleaves the transmembrane precursor of HB-EGF, and the released HB-EGF then binds to EGF receptors on heart muscle cells and stimulates their inappropriate growth. The excessive proliferation of

heart muscle cells can lead to an enlarged but weakened heart — a condition known as *cardiac hypertrophy*, which may cause early death. How cleavage of these proteins by ADAM metalloproteases is regulated and how specificity of substrate cleavage on the cell surface is achieved are still not completely understood. ■

KEY CONCEPTS OF SECTION 16.6

Signal Transduction Pathways That Utilize Regulated, Site-Specific Protein Cleavage: Notch/Delta and EGF Precursors

- On binding to its ligand, Delta, on the surface of an adjacent cell, the receptor Notch protein undergoes two proteolytic cleavages (see Figure 16-25), first by an ADAM protease and then within the plane of the plasma membrane by γ-secretase. The released Notch cytosolic segment then translocates into the nucleus and modulates transcription of target genes critical in determining cell fate during development.
- Many important growth factors and other signaling proteins such as EGFs are synthesized as transmembrane proteins; regulated cleavage of the precursor near the plasma membrane by members of the ADAM protease family releases the active molecule into the extracellular space to signal distant cells.
- Inappropriate cleavage of EGF-family precursors can result in abnormal cell proliferation, potentially leading to cancer, cardiac hypertrophy, and other diseases.

16.7 Signal Transduction Pathways That Utilize Proteasomal Degradation of Signaling Components: Wnt, Hedgehog, and the Many Hormones That Activate NF-κB

Next we discuss signal transduction pathways in which either a transcription factor or an inhibitor of a transcription factor becomes ubiquitinated and then is either cut or totally degraded by the proteasome. We begin with signal transduction pathways induced by the **Wnt** and **Hedgehog (Hh)** proteins, two evolutionarily conserved families of signaling proteins that play key roles in many developmental pathways and often induce expression of genes required for a cell to acquire a new identity or fate. Although Wnt and Hedgehog signaling pathways use different sets of receptors and signaling proteins, they do share similarities, which is why we group them together:

- In the unstimulated state, key transcription factors in both pathways are initially localized in large cytosolic multiprotein complexes; enzymes in the complex add ubiquitin chains to the transcription factors. In the Wnt pathway the transcription factor becomes totally degraded by the proteasome, whereas in

the Hh pathway the transcription factor is cleaved by the proteasome, generating a repressor of transcription.
- Activation of both pathways involves disassembly of these protein complexes, inhibition of cleavage or degradation of the transcription factor, and movement of the full-length, active transcription factor into the nucleus.
- Both pathways regulate cell fate decisions in animal development.

Next we examine the *NF-κB signal transduction pathway* that is activated downstream of many important hormones that affect the immune system. In this case, an inhibitor of a transcription factor, rather than a transcription factor itself, is degraded following ubiquitinylation. In the resting state, the transcription factor termed **NF-κB** is sequestered in the cytosol and bound to an inhibitor. Several signal transduction pathways, activated by different hormone receptors, converge on an enzyme that ubiquitinates and thus causes rapid degradation of the inhibitor. Freed of its inhibitor, NF-κB immediately and vigorously moves to the nucleus and activates transcription of multiple genes. In learning how the NF-κB pathway is activated by one class of surface receptors, we also see a very different function of polyubiquitinylation: the formation of a scaffold to assemble a key signal transduction complex.

Wnt Signaling Prevents Destruction of a Transcription Factor by a Cytosolic

Protein Complex

The components of the Wnt signaling pathways have been conserved throughout the evolution of metazoan organisms and were elucidated mainly through genetic analysis of developmental mutants in *Drosophila*. In vertebrates, mutations in these pathways are thought to trigger several types of cancers. In fact, the first vertebrate *Wnt* gene to be discovered, the mouse *Wnt-1* gene, attracted notice because it was overexpressed in certain mouse mammary cancers. When a mouse retroviral DNA, the mammary tumor virus (MMTV) genome, became inserted near the *Wnt-1* gene, the retrovirus LTR promoter (see Figure 7-13) activated inappropriate expression of the *Wnt-1* gene.

The human genome encodes 19 different Wnt proteins, and many Wnts are essential for critical developmental events, including bone formation, the segmented development of the musculoskeletal system in vertebrates, and the formation and maintenance of skin and hair. Yet all Wnt proteins are thought to use the same set of cell-surface receptors and signal transduction proteins.

Wnt proteins are signaling molecules secreted from the cell and are modified by linkage of a monounsaturated fatty acid, palmitoleic acid, to a serine in the middle of the protein. Like other secreted signaling proteins, Wnt proteins interact with several extracellular and cell-surface proteins and activate multiple downstream signal

transduction pathways. The principal signaling receptor for Wnt proteins is *Frizzled (Fz)*, which contains seven transmembrane α helices. Like the glucagon receptor (see Figure 15-15), Fz has a large extracellular domain that is connected to the first membrane-spanning α helix and contains the major Wnt binding site. Unlike the glucagon receptor, however, as far as is known Fz does not activate a G protein. The palmitoleate attached to the Wnt protein binds to a specific site on the Fz extracellular domain and stabilizes the Wnt-Fz complex. Thus this lipid is central to receptor engagement by Wnt proteins and is one of the few known examples of post-translational modification by a lipid that mediates a ligand-receptor interaction.

At least three different signal transduction pathways can be activated by the binding of different Wnt proteins to particular Fz proteins. The most widespread, canonical Wnt signaling pathway has a second transmembrane receptor, LRP (called *Arrow* in *Drosophila*), that associates with Fz such that Wnt binds simultaneously to both (Figure 16-26). Inactivating mutations in the genes encoding Wnt proteins, Fz, or LRP all have similar effects on the development of mouse embryos, indicating that all three proteins are essential for Wnt signaling.

FIGURE 16-26 Canonical Wnt signaling pathway. (a) In the absence of Wnt, the transcription factor TCF is bound to promoters or enhancers of Wnt target genes. Its activator β-catenin is absent from the nucleus, and TCF is associated with transcriptional repressor proteins such as Groucho (Gro) that inhibit gene transcription. The key signaling molecule in the canonical Wnt pathway is the cytoplasmic protein β-catenin, whose stability is controlled by a large multiprotein β-catenin destruction complex. The tumor suppressor protein Axin is the scaffold of the complex, and binds to β-catenin, the tumor suppressor APC, the Dishevelled (Dvl) protein, and two constitutively active protein kinases, glycogen synthase kinase 3β (GSK 3β) and casein kinase 1 (CK1). CK1 and GSK3 sequentially phosphorylate β-catenin at multiple serine and threonine residues. The E3 βTrCP ubiquitin ligase then binds to two phosphorylated residues on β-catenin, leading to ubiquitinylation of β-catenin and its degradation in proteasomes. (b) Wnt proteins bind to a complex of two receptor proteins on the cell surface, Frizzled (Fz) and LRP. Fz proteins have seven

transmembrane segments and an extracellular N-terminal domain that binds Wnt. Binding of Wnt to these receptors induces phosphorylation of the LRP cytosolic domain by several kinases, followed by binding of Axin to phosphorylated LRP and Dvl to Fz. This causes part of the Axin–APC–CK1–GSK3–β-catenin complex to fall apart, preventing phosphorylation of β-catenin by CK1 and GSK3, inhibiting ubiquitination of β-catenin, and allowing β-catenin to accumulate in the cytosol. After translocation to the nucleus, β-catenin binds to TCF, displaces the Gro repressor, and recruits co-activator proteins to activate expression of Wnt target genes. See R. Nusse and H. Clevers, 2017, *Cell* **169**:985; and also the Wnt home page, http://web.stanford.edu/group/nusselab/cgi-bin/wnt.

The central player in the canonical Wnt intracellular signal transduction pathway is a protein called *β-catenin* in vertebrates and *Armadillo* in *Drosophila*. This multi-talented protein functions both as a transcription factor in the Wnt signaling pathway and as a linker protein that connects cell adhesion proteins in the plasma membrane to the actin cytoskeleton (see Figure 20-14). In the absence of a Wnt signal, the β-catenin molecules that are not involved in membrane-cytoskeleton interactions ("free" β-catenin) are targeted for degradation by a cytosolic *destruction complex* that is held together by the scaffold protein Axin. This complex contains the tumor suppressor adenomatous polyposis coli (APC) protein, so named because its loss may result in colorectal cancer. The large size of the destruction complex observed by fluorescence microscopy suggests that it contains many copies of each component.

In the resting state, two constitutively active kinases in the destruction complex, casein kinase 1 (CK1) and GSK3, sequentially

phosphorylate β-catenin on multiple serine and threonine residues; some of these phosphorylated residues serve as binding sites for an E3 ubiquitin-ligase protein named *βTrCP*. β-Catenin is then ubiquitinylated by βTrCP and rapidly degraded by the 26S proteasome (Figure 16-26a; for more on ubiquitinylation, see Figure 3-32). Degradation prevents free β-catenin from entering the nucleus and activating transcription of Wnt target genes.

The complete mechanism by which Wnt signaling blocks the degradation of β-catenin, enabling it to act as a transcription factor, has not yet been fully elucidated. The formation of the Wnt/Fz/LRP complex at the cell surface causes the adaptor protein Dishevelled (Dvl), a component of the destruction complex, to bind to Fz and Axin to bind to LRP. This results in the destabilization and inactivation of the destruction complex — no phosphorylation or subsequent polyubiquitinylation of β-catenin. Thus free β-catenin accumulates; it transfers into the nucleus and activates transcription of Wnt target genes (Figure 16-26b).

Aberrant hyperactive Wnt signaling and abnormally high levels of free β-catenin is implicated in the progression of many cancers; the Wnt signaling pathway is hyperactive in more than 90 percent of human colon cancers (see Chapter 25). This observation provided one of the earliest clues that β-catenin can activate many growth-promoting genes. Inactivating mutations in genes encoding the tumor suppressors APC and Axin, components of the destruction

complex, are found in multiple types of human cancers, as are mutations in β-catenin phosphorylation sites for the destruction complex kinases GSK3 or CK1; these mutations either reduce the formation of the destruction complex or reduce the phosphorylations on β-catenin (see Figure 16-26a). Thus they reduce degradation of β-catenin and allow free β-catenin to activate gene expression even in the absence of the normal Wnt signal. ■

Among the Wnt target genes are many that also control Wnt signaling, indicating a high degree of feedback regulation. The importance of β-catenin stability and localization means that Wnt signals affect a critical balance between the three pools of β-catenin in the cell: at the membrane-cytoskeleton interface, in the cytosol, and in the nucleus.

Concentration Gradients of Wnt Protein Are Essential for Many Steps in Development

Wnts are proteins secreted from the cell; however, in part because of the hydrophobic lipid that is covalently linked to these proteins, these proteins diffuse only a short distance from a signaling cell and generally have only localized effects. As Wnt diffuses farther and farther away from secreting cells, its concentration decreases. Different Wnt concentrations induce different fates in target cells:

cells that detect a large amount of Wnt turn on certain genes and form certain structures; cells that detect a smaller amount turn on different genes and so form different structures. Signals that induce different cell fates depending on their concentration at their target cells are referred to as **morphogens**. In the development of the vertebrate nervous system, for instance, high levels of Wnt signaling specify that a certain progenitor cell becomes a posterior neuron while low levels of Wnt signaling specify that the progenitor cell becomes an anterior neuron.

A striking example of a Wnt gradient regulating tissue pattern occurs in the adult planarian *Schmidtea mediterranea* (see Figure 1-23e); Wnt mRNA and protein are expressed in a posterior-to-anterior gradient (Figure 16-27a). If the planarian's head is cut off, a new one regenerates within 14 days; a normal, albeit smaller, worm is regenerated. Similarly, after removal of the tail, a new one regenerates.

EXPERIMENTAL FIGURE 16-27 Gradients of Wnt are essential for normal regeneration of a head and a tail by planaria. (a) As shown by in situ hybridization, the *WntP-2* gene (pink dots) is expressed in a posterior-to-anterior gradient in adult planaria. J. Witchley et al., 2013, *Cell Rep.* **4**:633. (b) As indicated in the diagram, a small piece excised from the middle of the body of the planarian *S. mediterranea* was placed in culture. In situ mRNA hybridization performed after 4 days indicated that Wnt mRNA (pink dots) was expressed in cells at both the anterior and posterior wound sites, but that the Wnt inhibitor Notum (blue dots) was expressed only at the anterior wound site. Thus a posterior-to-anterior gradient of Wnt protein is formed. (c) After 14 days in culture, the excised body piece has regenerated a normal, albeit smaller, worm, with a head, easily visualized by the two eyes, from the anterior wound site and a tail from the posterior. Treatment of the excised body piece with an inhibitory RNA specific for β-catenin results in regeneration of a two-headed planarian, whereas treatment with an inhibitory RNA specific for Notum results in regeneration of a two-tailed planarian. Treatment of the excised body piece with two inhibitory RNAs, one specific for β-catenin and the other for Notum, results in a phenotype similar to that caused

by the loss of β-catenin alone: a two-headed planarian is regenerated. (d) These experiments give rise to a model in which β-catenin, stabilized by addition of Wnt to cells, causes expression of genes that promote tail formation; inhibition of Wnt/β-catenin signaling by Notum causes a head to be formed. [Part (a) photo: Jessica Witchley and Peter Reddien. Part (c, *left two photos*) Republished with permission from AAAS, from C. P. Petersen and P. W. Reddien, 2008, "Smed-β-catenin-1 Is Required for Anteroposterior Blastema Polarity in Planarian Regeneration," *Science* **319**(5861):327–330; photos courtesy of J. Witchley and Peter Reddien. Part (c, *right two photos*) Republished with permission from AAAS, from C. P. Petersen and P. W. Reddien, 2011, "Polarized *notum* Activation at Wounds Inhibits Wnt Function to Promote Planarian Head Regeneration," *Science* **332**(6031):852–855; permission conveyed through Copyright Clearance Center, Inc.; photos courtesy of J. Witchley and Peter Reddien.]

Strikingly, a small body piece taken from the middle of the animal regenerates a normal head from the anterior (head-facing) wound and a tail from the posterior wound (Figure 16-27b). Wnt signaling is required for the choice of head versus tail made at the wounds in these fragments. The gene *Wnt-1* is expressed at all planarian wounds. By contrast, the gene encoding the secreted extracellular enzyme *Notum* is expressed only at anterior-facing wounds. Notum inhibits Wnt signaling by cleaving off palmitoleic acid, the fatty acid that is covalently attached to Wnt and, as we learned above, is essential for Wnt signaling.

RNA interference (RNAi) can be used to inhibit either the *β-catenin* gene, eliminating Wnt signaling, or the *notum* gene, or both genes. As shown in Figure 16-27c, in the absence of all Wnt signaling, a two-headed planarian is regenerated. In contrast, in the absence of Notum, a two-tailed planarian is regenerated; in this case, Wnt is

present and active at both the anterior and posterior wounds, and thus two tails are formed. In the absence of both Wnt signaling and Notum, the phenotype is similar to that caused by the loss of Wnt alone: a two-headed planarian is regenerated. Wnt signaling is absent at both the anterior and posterior wounds, inducing head regeneration at both sites, and the absence of Notum is irrelevant in the absence of Wnt. These experiments show that Wnt/β-catenin signaling promotes tail regeneration and inhibits head regeneration; the absence of Wnt signaling induces head formation at wounds (Figure 16-27d).

In Chapter 22, we will learn that mature planarians contain pluripotent stem cells termed *neoblasts* that can differentiate into any body cell type. Gradients of Wnt protein play a major role in instructing neoblasts to differentiate into the appropriate cell types of tissues that constitute the planarian head or tail. As evidence, RNA interference (RNAi) has been used to specifically inhibit *β-catenin* throughout an uninjured animal. Even in these uninjured animals, inhibition of Wnt signaling by this means causes heads to appear around the body. These are consequences of defects in the pattern of tissue replacement and repair mediated by stem cells (see the chapter opening figure).

Hedgehog Signaling Relieves Repression of Target Gene Expression

The Hedgehog (Hh) signaling pathway is similar to the Wnt pathway in that two membrane proteins, one with seven membrane-spanning segments, are required to receive and transduce a signal. The Hh pathway also involves the disassembly of an intracellular complex containing a transcription factor. Hh signaling differs from Wnt signaling in that its two membrane receptors move between the plasma membrane and intracellular vesicles, and that in mammalian cells, the Hh signaling pathway is restricted to the single primary cilium that protrudes from the cell surface of most vertebrate cells.

Like Wnt proteins, Hh proteins contain a covalently attached lipid and often act as morphogens and signal to influence the fate of nearby cells. Hh signaling plays essential roles in the development of numerous organ systems in animals. For instance, Hh signaling specifies the identities of neurons made along the ventral (belly) to dorsal (back) axis of the embryonic neural tube, which makes the spinal cord and brain. Hh signaling also regulates lung morphogenesis and hair follicle formation. One of the three mammalian Hh proteins, Sonic Hedgehog (Shh), is essential for normal patterning of the limbs; abnormal expression of Shh in an anterior region of the developing limb, in addition to its normal expression in the posterior domain, leads to polydactyly (extra digits).

Processing of Hh Precursor Protein

Hedgehog proteins are formed from a precursor protein with autoproteolytic activity that enables the protein to cut itself in half while still in the endoplasmic reticulum. The cleavage produces an N-terminal fragment, which is subsequently secreted to signal other cells, and a C-terminal fragment, which is degraded. As shown in Figure 16-28, cleavage of the precursor is accompanied by covalent addition of the lipid cholesterol to the new carboxyl terminus of the N-terminal fragment. A second modification to Hedgehog, the addition of a palmitoyl group to the N-terminus, makes the protein even more hydrophobic.

FIGURE 16-28 Processing of Hedgehog (Hh) precursor protein. Cells synthesize a 45-kDa Hh precursor, which in the endoplasmic reticulum undergoes a nucleophilic attack by the thiol side chain of cysteine 258 (Cys-258) on the carbonyl carbon of the adjacent residue glycine 257 (Gly-257), forming a high-energy thioester intermediate. Enzyme activity in the C-terminal domain then catalyzes the formation of an ester bond between the hydroxyl group of cholesterol and glycine 257, cleaving the precursor into two

fragments. The N-terminal signaling fragment (blue) retains the cholesterol group and is also modified by the addition of a palmitoyl group to the N-terminus. Once Hh has been secreted, the two hydrophobic anchors may tether the processed Hh protein to the plasma membrane. See P. Thérond, 2012, *Curr. Opin. Cell Biol.* **24**:173.

Despite its hydrophobicity Hh proteins can travel relatively long distances — up to 300 μm in the developing vertebrate limb. Both Hh and Wnt are often anchored to the phospholipid monolayers of extracellular lipoprotein particles (see Figure 14-27 for the structure of a typical lipoprotein) via their attached lipid groups, and while anchored to these particles they can diffuse in extracellular spaces. However, the majority of the Hh proteins produced by a cell can remain bound to its plasma membrane; in such cases, Hh signals mainly by cell-cell contact. As with Wnt proteins, spatial restriction plays a crucial role in constraining the effects of Hh proteins.

The Hh Receptors Patched and Smoothened and the Downstream Signaling Pathway Were Initially Elucidated by Genetic Studies of *Drosophila* Development

Two membrane proteins, Smoothened (Smo) and Patched (Ptc), are required to receive a Hedgehog signal and transduce it to the cell

nucleus. Smo has seven membrane-spanning α helices, is a member of the GPCR superfamily of proteins, and is related in sequence to the Wnt receptor Fz. Ptc contains 12 transmembrane α helices and is most similar structurally to the Niemann-Pick C1 (NPC1) protein, a cholesterol-transporting member of the ABC superfamily of membrane transport proteins (see Table 11-3). Ptc is the receptor to which Hh binds, but Smo is the membrane protein that initiates the signal to the nucleus. One can think of the pathway as two series of steps: The binding of Hh to Ptc initiates a series of steps that brings Smo to the plasma membrane, and from there Smo initiates another series of steps that frees a transcription factor from a cytosolic complex.

Figure 16-29 depicts the current model of the Hedgehog pathway in *Drosophila*, where the pathway is known in the most detail. Early evidence supporting this model came from the study of fly embryos with loss-of-function mutations in the *hedgehog (Hh)* or *smoothened (Smo)* genes. Both types of mutant embryos have very similar developmental phenotypes; the name *hedgehog* came from the appearance of Hh mutant embryos, which were covered by an array of disorganized hairlike bristles that resembled the spines on hedgehogs, as a result of a defect in the patterning of body segments. Moreover, both the *Hh* and *Smo* genes are required to activate transcription of the same target genes (e.g., *patched* and *wingless*) during embryonic development. In contrast, loss-of-function mutations in the *patched* (*Ptc*) gene produce a quite

different phenotype, one similar to the effect of flooding the embryo with Hedgehog protein. These findings suggested that, in the absence of Hh, Ptc represses target genes by inhibiting a signaling pathway that requires Hh and Smo and is needed for gene activation. The additional observation that Smo is required for the transcription of Hh target genes in mutants lacking *patched* function places Smo downstream of Ptc in the Hh pathway. Together with biochemical experiments showing that Hh binds directly to Ptc, this genetic evidence indicates that, in the absence of Hh, Ptc blocks Smo-mediated activation of the transcription of Hh target genes. Binding of Hh to Ptc relieves this inhibition and permits the transcription of target genes.

FIGURE 16-29 Hedgehog signaling in *Drosophila*. (a) In the absence of Hedgehog (Hh), the Hh receptor protein Patched (Ptc) inhibits Smoothened (Smo), which is present largely in the membranes of internal vesicles. Smo becomes ubiquitinated and then is degraded in proteasomes. A cytosolic complex containing the kinase Fused (Fu); other kinases including

protein kinase A (PKA), glycogen synthase kinase 3β (GSK3β), and casein kinase 1 (CK1), the zinc-finger transcription factor Cubitis interruptus (Ci), and SUFU (Suppressor of Fu), a protein that binds to and inhibits Ci, is bound to a microtubule by the kinesin-related motor protein Costal-2 (Cos2). In this complex, Ci becomes phosphorylated in a series of steps catalyzed by PKA, GSK3β, and CK1. The phosphorylated Ci is then proteolytically cleaved by the ubiquitin-proteasome pathway, generating an N-terminal fragment Ci75, which is transported into the nucleus and functions as a transcriptional repressor of Hh target genes. (b) Hh binds to Ptc, causing Ptc to be endocytosed from the cell surface and degraded, thereby relieving the inhibition of Smo. Smo then moves to the plasma membrane and its cytosolic C-terminus is phosphorylated by PKA, CK1, and other kinases. Then the C-terminal segment of Smo binds Cos2, and Smo is stabilized from degradation. Both Fu and Cos2 become extensively phosphorylated, and most importantly, the Fu-Cos2-Ci complex dissociates. This leads to the stabilization of the full-length Ci, which moves into the nucleus, displaces the repressor Ci75 from the promoter of target genes, recruits the CREB-binding activator protein (CBP), and induces expression of target genes. The exact membrane compartments in which Ptc and Smo respond to Hh and function are unknown. See S. Goetz and K. Anderson, 2010, *Nat. Rev. Genet.* **11**:331; and R. Heck et al., 2016, *Development* **143**:367.

Subsequent immunostaining and subcellular fractionation studies showed that, in the absence of Hh, Ptc is enriched in the plasma membrane but Smo is found in membranes of internal vesicles (Figure 16-29a). Precisely how Ptc inhibits Smo function is poorly understood.

In the absence of Hh, a microtubule-bound complex containing several different proteins including Fu and Cos2 sequesters in the cytosol the zinc-finger transcription factor called, in *Drosophila*, *Cubitis interruptus (Ci)*. The protein complex contains at least four kinases, including the same two that phosphorylate β-catenin in the

Wnt pathway. Phosphorylation of Ci in this complex by these kinases triggers binding of a component of an E3 ubiquitin ligase complex, which in turn directs ubiquitinylation of Ci and its targeting to proteasomes. There Ci undergoes a specific proteolytic cleavage but not complete degradation to amino acids; the resulting Ci fragment, designated *Ci75*, translocates to the nucleus and *represses* expression of Hh target genes.

Following binding of Hh to the receptor Ptc, the Hh-Ptc complex, like many other receptor-ligand complexes, is endocytosed from the cell surface into internal vesicles and eventually degraded; the binding of Hh to Ptc also inhibits the ability of Ptc to inhibit Smo (Figure 16-29b). The now active Smo moves from internal vesicles to the plasma membrane, where it initiates the signaling pathway that sends the full-length transcription factor Ci to the nucleus. The C-terminal cytosol-facing domain of Smo becomes phosphorylated through the coordinated activities of several kinases. Then Cos2 binds to the phosphorylated C-terminal tail of Smo and itself becomes phosphorylated. This leads to a disruption of the cytosolic complex of Fu, Cos2, and Ci, and its dissociation from microtubules, triggering a reduction in both phosphorylation and proteolytic cleavage of Ci. As a consequence, full-length Ci is released from the dissociated complex and translocates to the nucleus, where it binds to the transcriptional co-activator CREB-binding protein (CBP), activating rather than repressing Hh target genes.

Feedback Regulation of Hh Signaling

As in other signaling pathways, feedback control of the Hh pathway is important because unrestrained Hh signaling can cause cancerous overgrowth or formation of the wrong cell types. In *Drosophila*, one of the genes induced by the Hh signal is *patched*. The subsequent increase in expression of Ptc dampens the Hh signal in large measure by reducing the pool of active Smo protein inside the cell and by sequestering Hh protein on the cell surface. Thus the system is buffered: if during development too much Hh signal is made, a consequent increase in Ptc will compensate; if too little Hh signal is made, the amount of Ptc produced is decreased.

Hedgehog Signaling in Vertebrates Requires Primary Cilia

The Hedgehog signaling pathway in vertebrates shares many conserved features with the *Drosophila* pathway, but there are also some striking differences. First, mammalian genomes contain three *Hh* genes and two *Ptc* genes, which are expressed differentially among various tissues. Second, mammals express three Gli transcription factors, which collectively perform the roles of the single Ci transcription factor in *Drosophila*. All other components of the Hh pathway in *Drosophila* also are conserved in mammals.

The most fascinating aspect of the mammalian Hh pathway is the involvement of the primary cilium. Cilia are long, thin structures enveloped by a plasma membrane that protrude from the cell surface. The roles of cilia and flagella in specialized cell types — such as moving materials along the airway surface formed by tracheal cells and powering the locomotion of sperm — are well known (see Figure 1-15 and Chapter 18). Most vertebrate cells have a single cilium called the *primary cilium*, a slim, nonmotile structure that projects from the surface, but primary cilia are conspicuously absent in almost all invertebrate cell types that have been examined.

As we will learn in Chapter 18, a cilium is extended and maintained by the transport of proteins and particles along a bundle of microtubules in its center; different intraflagellar transport (IFT) motor proteins move proteins and particles along the microtubule bundle from the base of the cilium to the tip and in the opposite direction. Some of the first evidence for a role of primary cilia in Hh signaling came from a screen for mutations in mice that altered early development in a manner similar to that seen in embryos with altered Hh signaling: the mutant phenotypes included losses of certain types of cells in the neural tube that require high concentrations of a particular Hh protein to develop. Many of these mutations were in genes encoding IFT proteins, indicating a role for cilia (or flagella) in Hh signaling.

Further studies showed that in the absence of Hh signaling, Ptc is localized to the membrane of the primary cilium and Smo is located in internal vesicles near the base of the cilium. As in *Drosophila*, in the absence of Hh, kinases in a cytosolic complex phosphorylate Gli, inducing cleavage of Gli by the proteasome and translocation of the Gli fragment (termed Gli^R) into the nucleus, where it binds to regulatory regions of Gli-responsive genes and *represses* their expression.

As a result of Hh binding to Ptc, Smo moves into the membrane of the primary cilium. Gli then accumulates at the tip of the cilium, a process requiring a kinesin motor protein (Chapter 18) to move material along microtubules to the tip of the cilium. At the cilia tip, Gli becomes activated by proteins attached to Smo by a mechanism not yet known in detail, but involving dissociation of Gli from Sufu, an inhibitor of Gli that is a component of the cytosolic complex. Another motor protein, in this case the retrograde motor dynein (Chapter 18), is required to move the full-length and activated Gli, (termed Gli^A) to the base of the cilium. As in *Drosophila*, this active transcription factor then moves into the nucleus, where it activates, rather than represses, expression of multiple target genes. The detailed mechanisms of Hh signaling and Gli activation remain unclear.

Ptc is predicted to transport cholesterol or a structurally related sterol that could either activate or inhibit Smo. The vertebrate Smo

protein can bind cholesterol as well as several kinds of oxysterol molecules, both by a site in its N-terminal extracellular segment and one within its membrane-spanning domain. As cholesterol is sufficient to activate vertebrate Smo, in vertebrates cholesterol or a related sterol, perhaps transported into the cytosol by Ptc, is likely to be the activator of Smo. In contrast, in *Drosophila*, cholesterol is not sufficient to activate Smo, and the identity of the activator for *Drosophila* Smo is completely unknown. Thus much remains to be learned about the mechanism of Smo activation both in flies and man!

Inappropriate activation of Hh signaling is the cause of several types of human tumors, including medulloblastomas (cerebellum tumors) and rhabdomyosarcomas (muscle tumors). Primary cilia are essential for this abnormal Hh signaling, and drugs that inhibit the function of primary cilia are being tested on animal models of these cancers. For instance, expression of a mutant activated form of Smo in the postnatal mouse brain causes medulloblastomas, but these tumors do not form if, simultaneously, a gene encoding an essential ciliary protein is inactivated. ■

Degradation of an Inhibitor Protein Activates the NF-κB Transcription Factor

As we have seen, in the non-stimulated state of the Wnt and Hh signal transduction pathways, a key transcription factor is ubiquitinylated and subjected to limited proteolytic cleavage or complete degradation; activation of the signaling pathway blocks ubiquitinylation and releases the transcription factor in its active state. The NF-κB pathway works in the opposite manner: in the resting state, the NF-κB transcription factor is retained in the cytosol bound to an inhibitor; activation of the signaling pathway results in the inhibitor becoming ubiquitinylated and then degraded, triggering release of the active transcription factor. This mechanism allows cells to respond to a variety of stress signals by quickly activating gene transcription. The steps in the NF-κB pathway were revealed in studies with both mammalian cells and *Drosophila*.

The NF-κB signaling pathway is named for its key transcription factor NF-κB (an acronym for the somewhat unwieldy descriptor "*n*uclear-*f*actor *k*appa-light-chain enhancer of activated *B* cells"). This transcription factor is rapidly activated in many mammalian immune-system cells in response to bacterial and viral infection, inflammation, and a number of other stressful situations, such as ionizing radiation. In certain cells of the immune system, for example, the NF-κB pathway is activated when components of bacterial or fungal cell walls or segments of bacterial DNA bind to certain *Toll-like receptors* on the cell surface or in endosomal membranes (see Figure 24-37). In several types of cells, this pathway is activated by so-called inflammatory cytokines, such as *tumor*

necrosis factor alpha (TNFα) and *Interleukin 1 (IL-1)*, which are released by nearby immune cells in response to infection. In all of these cases, binding of ligand to its receptor induces a signaling pathway that activates the NF-κB transcription factor.

NF-κB was originally discovered on the basis of its transcriptional activation of the gene encoding the light chains of antibodies (immunoglobulins) in B cells. It is now thought to be a master transcriptional regulator of the immune system in mammals. Although flies do not make antibodies, NF-κB homologs in *Drosophila* induce synthesis of a large number of secreted antimicrobial peptides in response to bacterial and viral infection. The existence of these homologs indicates that the NF-κB regulatory system has been conserved during evolution and is more than half a billion years old.

Biochemical studies in mammalian cells and genetic studies in flies have provided important insights into the operation of the NF-κB pathway. The NF-κB transcription factor is a heterodimer formed of two subunits, p65 and p50. These two subunits share a region of homology at their N-termini that is required both for their dimerization and binding to DNA. In cells that are not undergoing a stress or responding to signs of an infection, NF-κB binds directly to an inhibitor called *I-κBα* and by this linkage is sequestered in an inactive state in the cytosol. A single molecule of I-κBα binds to the

paired N-terminal domains of the p50–p65 subunits, thereby masking their nuclear-localization signals (Figure 16-30).

FIGURE 16-30 Activation of the NF-κB signaling pathway. In resting cells, the heterodimeric transcription factor NF-κB, composed of p50 and p65 subunits, is sequestered in the cytosol, bound to the inhibitor protein I-κBα. Step **1**: As indicated by the arrows, the three-subunit I-κB kinase is activated downstream of signal transduction pathways stimulated by diverse agents, including activation of any of several Toll-like receptors (Figure 24-37), and by components of invading viruses, bacteria, or fungi. Step **2**: The β subunit of I-κB kinase phosphorylates the inhibitor protein I-κBα, creating a binding site on I-κBα for an E3 ubiquitin ligase. Steps **3** and **4**: Subsequent lysine 48–linked polyubiquitinylation of I-κBα targets it for degradation by proteasomes. Step **5**: The removal of I-κBα unmasks the nuclear-localization signals in both subunits of NF-κB, allowing their translocation to the nucleus. Step **6**: In the nucleus, NF-κB activates transcription of numerous target genes, including the gene encoding I-κBα, which acts to terminate signaling, and, depending on the

cell, activates genes encoding various inflammatory cytokines and other proteins. See R. Khush et al., 2001, *Trends Immunol.* **22**:260; and J. L. Luo et al., 2005, *J. Clin. Invest.* **115**:2625.

A three-protein complex termed *I-κB kinase* operates immediately upstream of NF-κB and is responsible for releasing it from sequestration. Activation of the kinase activity of the β subunit of I-κB kinase, abbreviated *IKKβ*, is the point of convergence of all of the extracellular signals noted above that activate NF-κB. Within minutes of stimulation of the cell by an infectious agent or inflammatory cytokine, the β subunit of I-κB kinase becomes activated by phosphorylation and then it phosphorylates two N-terminal serine residues on I-κBα (Figure 16-30, steps **1** and **2**). An E3 ubiquitin ligase then binds to these phosphoserines and ubiquitinylates I-κBα. This E3 ubiquitin ligase links the carboxyl terminus of one ubiquitin to lysine 48 (K48) on another, forming poly-K48-linked ubiquitin chains that target the attached I-κBα protein to the proteasome and its immediate degradation (steps **3** and **4**; also see Chapter 3). In cells expressing mutant forms of I-κBα in which these two serines have been changed to alanine and so cannot be phosphorylated, NF-κB is permanently inactive, demonstrating that phosphorylation of I-κBα is essential for pathway activation.

The degradation of I-κBα exposes the nuclear-localization signals on the two NF-κB subunits, which then translocate into the nucleus and activate transcription of a multitude of target genes (Figure 16-30,

steps 5 and 6). NF-κB signaling is eventually turned off by negative feedback regulation because one of the genes whose transcription is immediately induced by NF-κB encodes I-κBα. As its levels increase, the I-κBα protein binds active NF-κB in the nucleus and returns it to the cytosol.

In many immune-system cells, NF-κB stimulates transcription of more than 150 genes, including those encoding cytokines and chemokines; the latter attract other immune-system cells and fibroblasts to sites of infection using the signal transduction pathways we described earlier. NF-κB also promotes expression of receptor proteins that enable neutrophils (a type of white blood cell) to migrate from the blood into the underlying tissue (see Figure 20-42). In certain immune cells, NF-κB stimulates expression of iNOS, the inducible isoform of the enzyme that produces nitric oxide, which is toxic to bacterial cells, as well as expression of several anti-apoptotic proteins, which prevent cell death. Thus this single transcription factor coordinates and activates the body's defense, either directly by responding to pathogens and stress or indirectly by responding to signaling molecules released from other infected or wounded tissues and cells.

Enormous Signalsomes with Polyubiquitin Chain Scaffolds Link Many Cell Surface Receptors to

Downstream Proteins in the NF-κB Pathway

As we have just seen, activation of the β subunit of I-κB kinase is the point of convergence for extracellular signals transmitted through multiple receptors, including Toll-like and IL-1 receptors. Since the cytosolic domains of the Toll-like and IL-1 receptors have no enzyme activity, it was a mystery for many years how activation of these receptors led to phosphorylation and activation of the I-κB kinase β subunit. Recent work showed that huge multiprotein complexes termed *signalsomes* are formed by activation of these receptors and that several kinases incorporated into these complexes phosphorylate and thus activate I-κB kinase.

Oligomerization occurs at multiple levels of the signal transduction cascade, as exemplified by the IL-1 signalsome (Figure 16-31). An MyD88 *adapter* protein binds to the cytosolic domain of the ligand-activated IL-1 receptor, triggering formation of long helical filaments formed by interactions between MyD88 proteins and the kinases IRAK 2 (*I*nterleukin 1 *r*eceptor-*a*ssociated *k*inase 2) and IRAK4. TRAF6 proteins form homotrimers each of which then bind to three molecules of IRAK 2, the proteins at the ends of these filaments, and the tips of adjacent TRAF6 trimers bind together forming large two-dimensional lattices containing thousands of copies of TRAF6 and the other signalsome proteins.

FIGURE 16-31 The giant interleukin 1 (Il-1) signalsome and activation of NF-κB. Like the cytosolic domains of the Toll-like receptors (Figure 24-37), the cytosolic domains of both subunits of the interleukin-1β (IL-1β) receptors contain a globular TIR domain; binding of IL-1β to interleukin 1 receptors triggers dimerization. MyD88 (red) proteins then bind to the receptors through interactions with the TIRs, and this in turn facilitates the successive binding of many copies of the kinases IRAK4 (green) and IRAK1 or IRAK2 (orange), leading to phosphorylation and activation of their kinase activities. Activated IRAK1 or IRAK2, in turn, binds TRAF6, an E3 ubiquitin ligase, to the signalsome, and

promotes the formation of an extended two-dimensional lattice formed by TRAF6-TRAF6 interactions. TRAF6 also catalyzes synthesis of long lysine-63-linked polyubiquitin chains that are covalently linked to TRAF6 itself. Several proteins including the protein kinase TAK1 and the protein NEMO bind to these K-63 linked polyubiquitin chains. NEMO (a component of the I-κB kinase complex depicted in Figure 16-30), in turn, recruits IKK kinases α and β to the complex, forming the three subunit I-κB kinase complex. IKK α and β kinases then become activated by phosphorylation by TAK1 or other active kinases in the supramolecular complex. As depicted in Figure 16-30, the β subunit of I-κB kinase then phosphorylates the inhibitor I-κB, leading to proteasome destruction of I-κBα and activation of the NF-κB signaling pathway. Only a small portion of an actual signalsome is depicted in this figure as the free ends of the TRAF6 proteins will bind to other TRAF6 molecules, expanding the area of the signalsome just inside the plasma membrane.

[Data from R. Ferrao et al., 2012, *Sci. Signal.* **5**:re3; B. Skaug et al., 2009, *Annu. Rev. Biochem.* **78**:769; and J. Napetschnig and H. Wu, 2013, *Annu. Rev. Biophys.* **42**:443.]

TRAF6 is an E3 ubiquitin ligase that synthesizes polyubiquitin chains. At the time TRAF6 was discovered all polyubiquitinylation was thought to signal degradation by proteasomes, so researchers looked for ubiquitinylated target proteins that were quickly destroyed. Not finding these, scientists looked for other possible roles for polyubiquitin and soon found that, depending on the specific E3 ubiquitin ligase, multiple types of polyubiquitin chains are formed that have different structures and biological functions. The E3 ligase TRAF6 links the carboxyl terminus of one ubiquitin to lysine 63 (K63) on another ubiquitin (see Figure 3-39), forming a linear poly-K63 ubiquitin chain. Rather than targeting the protein to which it is attached for degradation, these ubiquitin chains act as

scaffolds that bind proteins that have a *poly-K63 ubiquitin-binding domain*. One of these proteins is the protein kinase TAK1, which becomes activated by binding to the polyubiquitin chain; another is the NEMO subunit of the I-κB kinase. Binding to adjacent sites on the poly-K63 ubiquitin brings the TAK1 kinase and its target, the β subunit of I-κB kinase, into proximity so that TAK1 can phosphorylate and thereby activate this downstream kinase (see Figure 16-31). I-κB kinases can also become activated by phosphorylation by other already active I-κB kinases in the complex. As noted above, I-κB kinase then phosphorylates I-κBα, leading to activation of the NF-κB factor. Thus two different types of polyubiquitin chains participate in very different ways in transmitting the IL-1 signal to activation of the NF-κB transcription factors.

What is the advantage of such huge signalsome complexes? Why did they evolve as part of signal transduction pathways downstream of Toll-like receptors and receptors for many inflammatory hormones, including IL-1 and TNFα? One hypothesis is that many hormone receptors must cooperate to form signalsomes, leading to a threshold all-or-none response: a low concentration of an extracellular signal would not trigger assembly of a stable functional signalsome whereas just a slightly higher concentration would trigger a maximum response. This prevents the immune system from mounting a potentially damaging immune response in the absence of significant danger. Depending on the TNFα

concentration, formation of the signalsome by the TNFα receptor can take between 20 and 50 minutes, and this delay allows formation of a signalsome to be reversed if the initial stimulation does not persist. Such a fail-safe mechanism might have evolved to allow a response only when there is sufficient danger, as signaled by a persistent and high dose of stimulation.

KEY CONCEPTS OF SECTION 16.7

Signal Transduction Pathways ThatUtilize Proteasomal Degradation of Signaling Components: Wnt, Hedgehog, and the Many Hormones That Activate NF-κB

- Many signaling pathways involve ubiquitinylation and proteolysis of target proteins and so are irreversible or only slowly reversible. These target proteins can be either a transcription factor or an inhibitor of a transcription factor.
- Wnt signaling controls numerous critical developmental events, such as brain development, limb patterning, and organogenesis. Like Wnt, Hedgehog (Hh) also functions as a morphogen during development. Activating mutations in both pathways can cause cancer.
- Both Hh and Wnt are secreted proteins that contain lipid anchors that reduce their signaling ranges. The fatty acid covalently attached to Wnt is essential for binding to its Frizzled (Fz) receptor.
- Wnt signals act through two cell-surface proteins, the receptor Fz and co-receptor LRP, and an intracellular complex containing β-catenin (see Figure 16-26). Binding of Wnt promotes the stability and nuclear localization of β-catenin, which either directly or indirectly promotes activation of the TCF transcription factor.
- Gradients of Wnt protein concentration are essential for many steps in development, including regeneration of a head and tail in planaria (see Figure 16-27).
- The Hh signal also acts through two cell-surface proteins, Smoothened (Smo) and Patched (Ptc), and an intracellular complex containing the Cubitis interruptus (Ci) transcription factor (see Figure 16-29). An activating form of Ci is generated in the presence of Hh; a repressing Ci fragment is generated in the absence of Hh. Both Ptc and Smo change their subcellular location in response to Hh binding to Ptc.

- Hh signaling in vertebrates requires primary cilia and intraflagellar transport proteins. Ptc localizes to the ciliary membrane in the absence of Hh, and Smo moves from internal membranes to the cilium membrane when Hh is present.
- The NF-κB transcription factor regulates many genes that permit immune system cells to respond to infection and inflammation.
- In unstimulated cells, NF-κB is localized to the cytosol, bound to the inhibitor protein I-κBα. In response to many types of extracellular signals, I-κBα is phosphorylated and then ubiquitinylated, targeting it for degradation by proteasomes. The destruction of I-κBα releases active NF-κB, which translocates to the nucleus (see Figure 16-30).
- Signal transduction by the interleukin 1 and Toll-like receptors involves formation of huge multiprotein complexes termed *signalsomes*. Polyubiquitin chains formed by the TRAF6 protein in this complex form a scaffold that brings the TAK1 kinase near its substrate, the β subunit of the I-κB kinase, activating the I-κB kinase that phosphorylates the inhibitor I-κBα. The resultant destruction of I-κBα allows signals to be transmitted from the receptor to downstream components of the NF-κB pathway (see Figure 16-31).

Review the Concepts

1. Even though GRB2 lacks intrinsic enzyme activity, it is an essential component of the epidermal growth factor (EGF) signaling pathway that activates MAP kinase. What is the function of GRB2? What roles do the SH2 and SH3 domains play in the function of GRB2? Many other signaling proteins possess SH2 domains. What determines the specificity of SH2 interactions with other molecules?
2. Once an activated signaling pathway has elicited the proper changes in target-gene expression, the pathway must be inactivated. Otherwise, pathological consequences may result, as exemplified by persistent growth factor–initiated signaling in many cancers. Many signaling pathways possess intrinsic negative feedback by which a downstream event in a pathway turns off an upstream event. Describe the negative feedback that down-regulates signals induced by (a) erythropoietin and (b) TGF-β.

3. A mutation in the Ras protein renders Ras constitutively active (Ras^D). What is constitutive activation? How does constitutively active Ras promote cancer? What type of mutation might render the following proteins constitutively active: (a) Smad3, (b) MAP kinase, and (c) NF-κB?
4. The enzyme Ste11 participates in several distinct MAP kinase signaling pathways in the budding yeast *Saccharomyces cerevisiae*. What is the substrate for Ste11 in the mating factor signaling pathway? When a yeast cell is stimulated by mating factor, what prevents the induction of osmolytes required for survival in high-osmotic-strength media, given that Ste11 also participates in the MAP kinase pathway initiated by high osmolarity?
5. Describe the events required for full activation of protein kinase B.
6. Describe the function of the PTEN phosphatase in the PI-3 kinase signaling pathway. Why does a loss-of-function mutation in PTEN promote cancer? Predict the effect of constitutively active PTEN on cell growth and survival.
7. Name three features common to the activation of cytokine receptors and receptor tyrosine kinases. Name one difference with respect to the enzyme activity of these receptors.
8. Erythropoietin (Epo) is a hormone that is produced naturally in the body in response to low O_2 levels in the blood. The intracellular events that occur in response to Epo binding to its cell-surface receptor are well characterized. What molecule translocates from the cytosol

to the nucleus after (a) JAK2 activates STAT5 and (b) GRB2 binds to the Epo receptor? Why did some endurance athletes use Epo to improve their performance ("blood doping") until it was banned by most sports?

9. Explain how expression of a dominant-negative mutant of JAK blocks the erythropoietin (Epo)-cytokine signaling pathway.
10. Binding of TGF-β to its receptors can elicit a variety of responses in different cell types. For example, TGF-β induces plasminogen activator inhibitor 1 in epithelial cells and specific immunoglobulins in B cells. In both cell types, Smad3 is activated. Given the conservation of the signaling pathway, what accounts for the diversity of the response to TGF-β in various cell types?
11. How is the signal generated by binding of TGF-β to cell-surface receptors transmitted to the nucleus, where changes in target-gene expression occur? What activity in the nucleus ensures that the concentration of active Smads closely reflects the level of activated TGF-β receptors on the cell surface?
12. What feature of Delta ensures that only neighboring cells are signaled?
13. What biochemical reaction is catalyzed by γ-secretase?
14. The extracellular signaling protein Hedgehog can remain anchored to cell membranes. What modifications to Hedgehog enable it to be membrane bound? Why is this property useful?

15. Explain why loss-of-function *hedgehog* and *smoothened* mutations yield the same phenotype in flies, but a loss-of-function *patched* mutation yields the opposite phenotype.
16. Why is the signaling pathway that activates NF-κB considered to be relatively irreversible compared with cytokine or RTK signaling pathways? Nonetheless, NF-κB signaling must be down-regulated eventually. How is the NF-κB signaling pathway turned off?
17. Describe two roles for polyubiquitinylation in the NF-κB signaling pathway.

CHAPTER 17

Cell Organization and Movement I: Microfilaments

Courtesy Thomas Deerinck and Mark Ellisman.

A section of mouse intestine stained for actin (red), the extracellular matrix protein laminin (green), and DNA (blue). Each blue dot of DNA indicates the presence of a cell. Actin in the microvilli on the apical end of the epithelial cells can be seen lining the surface facing the lumen (*top*). Actin can also be seen prominently in the smooth muscle that surrounds the intestine (*bottom*).

OUTLINE

17.1 Microfilaments and Actin Structures
17.2 Dynamics of Actin Filaments
17.3 Mechanisms of Actin Filament Assembly
17.4 Organization of Actin-Based Cellular Structures
17.5 Myosins: Actin-Based Motor Proteins
17.6 Myosin-Powered Movements
17.7 Cell Migration: Mechanism, Signaling, and Chemotaxis

When we look through a microscope at the diversity of cells in nature, the variety of cell shapes and movements we see is astonishing. We may notice that some cells, such as vertebrate sperm, ciliates such as *Tetrahymena*, or flagellates such as *Chlamydomonas*, swim rapidly, propelled by cilia and flagella. Other cells, such as amoebae and human macrophages, move more sedately, propelled not by external appendages, but by coordinated movement of the cell itself. If we examine tissues under the microscope, we might notice that some cells connect to form a pavement-like sheet, whereas other cells — neurons, for example — have processes up to 3 feet in length that make selective contacts with other cells. When we look at the internal organization of cells, we see that organelles have characteristic locations. For example, the Golgi complex is generally near the nucleus, which itself is found in the center of the cell. How is this diversity of shape, cellular organization, and motility achieved? Why is it important for cells to have a distinct shape and well-defined internal organization?

To begin to answer these questions, let us consider two very different cells: epithelial cells and macrophages.

The epithelial cells that line the intestine form a tight, pavement-like layer of brick-shaped cells, known as an *epithelium* (Figure 17-1a, b). The epithelium imports nutrients from the intestinal lumen across the apical (*top*) domain of the plasma membrane and exports the nutrients across the basolateral (*bottom-side*) domain of the plasma membrane toward the bloodstream. To perform this directional transport, the apical and basolateral domains of the plasma membranes of epithelial cells contain different transport proteins.

FIGURE 17-1 Overview of the cytoskeletons of an epithelial cell and a migrating cell. (a) Transmission electron micrograph of a thin section of an epithelial cell from the small intestine, showing the core bundles of microfilaments that provide support to the microvilli. (b) Epithelial cells are highly polarized, with distinct apical and basolateral domains. An intestinal epithelial cell transports nutrients into the cell through the apical domain and out of the cell across the basolateral domain. (c) Transmission electron micrograph of part of the leading edge of a migrating cell. The cell was treated with a mild detergent to dissolve the membranes, which also allows solubilization of most cytoplasmic components. The remaining cytoskeleton was shadowed with platinum and visualized in the electron microscope. Note the network of actin filaments visible in this micrograph. (d) A migrating cell, such as a fibroblast or a macrophage, has morphologically distinct domains, with a leading edge at the front. Microfilaments are indicated in red, microtubules in green, and intermediate filaments in dark blue. The position of the nucleus (light blue oval) is also shown.

[Part (a) M. S. Mooseker and L. G. Tilney, 1975, *J. Cell Biol.* **67**(3):725–743; https://doi.org/10.1083/jcb.67.3.725. Part (c) T. M. Svitkina and G. G. Borisy, 1999, *J. Cell Biol.* **145**(5):1009–1026; https://doi.org/10.1083/jcb.145.5.1009.]

Epithelial cells are sealed together by cell junctions (discussed in Chapter 20), which create a physical barrier between the apical and basolateral domains of the membrane. This separation allows the cell to place the proper transport proteins in the appropriate places: either the apical or the basolateral membrane. In addition, the apical membrane domain has a unique morphology, with numerous fingerlike projections called microvilli that dramatically increase the area of the plasma membrane available for nutrient absorption. So we see that the distinct functions of different regions of the intestinal epithelium are due to specific morphological features. To achieve these features (such as membrane domains, microvilli, and cell junctions), epithelial cells must have an internal structure that gives the cells shape, promotes cell-to-cell adhesion, and aids in delivering the right proteins to the right membrane domain.

Now consider the macrophage, a type of white blood cell that seeks out infectious agents and destroys them by an engulfing process called *phagocytosis*. For example, bacteria release chemicals that attract the macrophage and guide it to the site of infection. As the macrophage follows the chemical gradient, twisting and turning to get to the bacteria and phagocytose them, it must constantly reorganize its cell locomotion machinery. As we will see, the internal machinery of macrophages that allows them to crawl across

a substrate is always oriented in the direction in which they crawl (Figure 17-1c, d).

These are just two examples of **cell polarity**, the ability of a cell to generate functionally distinct regions within itself. In fact, as you think about various types of cells, you might realize that most of them have some form of cell polarity. A universal example of cell polarity is the ability of cells to divide — they must first select an axis for cell division and then set up the machinery to segregate their organelles along that axis.

The shape, internal organization, and functional polarity of a cell are due to a network of filamentous proteins called the **cytoskeleton**. We can visualize the cytoskeleton in different ways. For example, the cytoskeleton can be visualized by electron microscopy after treating cells with gentle detergents that solubilize the plasma membrane and internal organelles, releasing most of the cytoplasm (see Figure 17-1c). The cytoskeleton can also be visualized by immunofluorescence microscopy, as shown in Figure 17-2. We know from various studies that the cytoskeleton extends throughout the cell and is attached to the plasma membrane and to internal organelles. Thus the cytoskeleton provides a framework for organizing cellular components and processes. The term *cytoskeleton* may imply a fixed structure like a bony skeleton in vertebrates. In fact, the cytoskeleton can be very dynamic, with components reorganizing in less than a minute under some conditions. Under

different conditions, it can be stable for hours. As we will see throughout this chapter, the lengths of cytoskeletal filaments and the dynamics of filament assembly vary both in different regions of the cell and depending on the needs of the cell. The result is that cytoskeletal filaments are assembled into many types of structures and are regulated within different regions of the cell.

FIGURE 17-2 The components of the cytoskeleton. Each filament type is assembled from specific subunits in a reversible process so that cells can assemble and disassemble filaments as needed. Bottom panels show localization of the three filament systems in cultured cells as seen by immunofluorescence microscopy of actin, tubulin, and an intermediate filament protein, respectively. The image of microtubules shows their distribution in an interphase cell. In mitosis, they make up the machinery for chromosome segregation, as we discuss in Chapter 18.

The cytoskeleton is composed of three different filament systems, shown in Figures 17-1b, 17-1d, and 17-2. The filaments are polymers whose assembly and disassembly are regulated. This gives the cell flexibility to assemble and disassemble different types of cytoskeletal structures as needed. The three filament systems are:

- **Microfilaments** are polymers of the protein *actin* that are organized into functional bundles and networks by actin-binding proteins. Microfilaments are especially important in organizing the plasma membrane, giving shape to surface structures such as microvilli. Microfilaments can provide mechanical support on their own or can serve as tracks for ATP-powered myosin **motor proteins**. Myosin can ferry cargo along microfilaments, and myosin and microfilaments working together provide a contractile function (as in muscle).
- **Microtubules** are polymeric tubes formed from the protein *tubulin* and organized by microtubule-associated proteins. Microtubules make up the mitotic spindle, the machine for segregating duplicated chromosomes at mitosis. In interphase cells, as shown in Figure 17-2, microtubules often extend throughout the cell, providing a framework for the organization of organelles and structural support to cilia and flagella. Motor proteins called *kinesins* and *dyneins* transport cargo along microtubules, and like myosins, they are powered by ATP hydrolysis.
- **Intermediate filaments** are also polymers, but assembled from tissue-specific subunits that lend structural support to the nuclear membrane, provide structural integrity to cells in tissues, and serve structural and barrier functions in skin, hair, and nails. Unlike microfilaments and microtubules, intermediate filaments are not used as tracks by motor proteins.

As we can see in Figure 17-1, cells can organize their cytoskeletons in distinct ways. How cells organize the cytoskeleton depends on the

cells' ability to sense signals — from soluble factors bathing the cell, from adjacent cells, or from the extracellular matrix — and interpret them (Figure 17-3). These signals are detected by cell-surface receptors that activate signal transduction pathways, which ultimately converge on factors that regulate cytoskeletal organization.

FIGURE 17-3 Regulation of cytoskeleton function by cell signaling. Cells use cell-surface receptors to sense external signals from the extracellular matrix, other cells, or soluble factors. These signals are transmitted across the plasma membrane and activate specific cytosolic signaling pathways. Signals — often integrated from more than one receptor — lead to the organization of the cytoskeleton so as to provide cells with their shape as well as to determine organelle distribution and movement. In the absence of external signals, cells still organize their internal structure, but not in a polarized manner.

The importance of the cytoskeleton for normal cell function and motility is evident when a defect in a cytoskeletal component — or in cytoskeletal regulation — causes disease. For example, about 1 in 500 people has a cytoskeletal defect that affects the contractile apparatus of the heart resulting in various cardiomyopathies (diseases of the heart muscle). Many defects in red blood cytoskeletal components that support these cells' plasma membrane are known to cause disease. Metastatic cancer cells break away from their tissue of origin and migrate to new locations because of misregulation of the cytoskeleton.

In this and the following chapter, we discuss the structure, function, and regulation of the cytoskeleton. We look at how a cell arranges its cytoskeleton to generate cell shape and cell polarity to provide organization and motility to its organelles and to be the structural framework for such processes as cell swimming and cell crawling. We discuss how cells assemble the three different filament systems and how signal transduction pathways regulate these structures. Regulation of the cytoskeleton during the cell cycle is discussed in Chapter 19. In Chapter 20, we examine how the cytoskeleton participates in the functional organization of tissues. Our focus in this current chapter is on microfilaments and actin-based structures. Although we initially examine the three cytoskeletal systems separately, in the next chapter we will see that microfilaments cooperate with microtubules and intermediate filaments in the normal functioning of cells.

17.1 Microfilaments and Actin Structures

Microfilaments can assemble into a wide variety of structures within a cell (Figure 17-4a). Each of these structures is critical for particular cellular functions. For example, microfilaments can form a tight bundle of filaments making up the core of the fingerlike **microvilli**, but they can also be found in a less ordered network just beneath the plasma membrane, in a region of cytoplasm known as the *cell cortex*, where they provide support and organization to membrane proteins. In epithelial cells, microfilaments form a contractile band around the cell, the *adherens belt*, that provides strength to the epithelium. In migrating cells, a network of microfilaments is found at the front of the cell in the **leading edge**, or **lamellipodium**, from which bundles of filaments called **filopodia** may protrude. Many cells have contractile microfilaments called **stress fibers**, which attach to the external substratum as cells migrate (discussed in Chapter 20). Specialized cells such as macrophages use contractile microfilaments to engulf and internalize pathogens though phagocytosis. Highly dynamic, short bursts of actin filament assembly can power the movement of *endocytic vesicles* away from the plasma membrane. At a late stage of cell division in animals, after all the organelles have been duplicated and segregated, a *contractile ring* forms and constricts to generate two daughter cells in the process of *cytokinesis*. Thus cells use actin filaments in many

ways: in structural roles, as contractile mechanisms, by harnessing actin polymerization and depolymerization to do work, and to move vesicles around within a cell. Multiple arrangements of microfilaments often coexist within a single cell, as shown in a migrating fibroblast (Figure 17-4b).

FIGURE 17-4 Examples of microfilament-based structures. (a) In each panel, microfilaments are depicted in red. (b) A cell moving toward the top of the page, stained for actin with fluorescent phalloidin, a drug that specifically binds F-actin. Note how many different organizations of microfilaments can exist in one cell.

The basic building block of microfilaments is **actin**, a protein that has the remarkable capacity to reversibly assemble into a polarized filament with functionally distinct ends. These filaments are molded into the various structures described in the previous paragraph by actin-binding proteins. The name *microfilament*, which arose from the very thin filaments seen by electron microscopists in thin-

section preparations of cells, refers to actin in its polymerized form, with its associated proteins. In this section, we look at the actin protein itself and the filaments into which it assembles.

Actin Is Ancient, Abundant, and Highly Conserved

Actin is an abundant intracellular protein in eukaryotic cells. In muscle cells, for example, actin constitutes 10 percent by weight of the total cellular protein; even in nonmuscle cells, actin makes up 1–5 percent of the cellular protein. The cytosolic concentration of actin in nonmuscle cells ranges from 0.1 to 0.4 mM. In structures such as microvilli, however, the local actin concentration can be as high as 5 mM. To grasp how much actin is present in cells, consider a typical liver cell, which has 2×10^4 insulin receptor molecules but approximately 5×10^8, or half a billion, actin molecules. Because they form structures that extend across large parts of the cell interior, cytoskeletal proteins are among the most abundant proteins in a cell.

Actin is encoded by a gene family that gives rise to some of the most conserved proteins within and across species. The protein sequences of actins from amoebae and from animals are identical at 80 percent of their amino acid positions, despite about a billion years of evolution. The multiple actin genes found in modern

eukaryotes are related to a bacterial gene, *MreB*, whose product forms filaments that are important in bacterial cell-wall synthesis. Some single-celled eukaryotes, such as yeasts and amoebae, have one or two actin genes, whereas multicellular organisms often contain multiple actin genes. For instance, humans have 6 actin genes, while *Arabidopsis* has 8 to 10, and maize has 21 actin genes. Each functional actin gene encodes a different isoform of the protein. In vertebrates, four actin isoforms are present in specific types of muscle cells, and two other isoforms are found in nonmuscle cells. These six isoforms differ at only about 25 of the 375 residues in the complete protein or show about 93 percent identity. Actin isoforms have historically been classified into three groups based on their overall charge: the α-actins, β-actins, and γ-actins. Alpha-actins are associated with various contractile structures, β-actins are enriched in the cell cortex and leading edge of motile cells, and γ-actin is found in stress fibers.

G-Actin Monomers Assemble into Long, Helical F-Actin Polymers

Actin exists as a globular monomer called *G-actin* and as a filamentous polymer called *F-actin*, which is a linear chain of actin subunits. Each actin molecule contains a Mg^{2+} ion complexed with either ATP or ADP. In fact, actin is an ATPase, which hydrolyzes ATP

to ADP and P_i. The importance of the interconversion between the ATP and the ADP forms of actin is discussed below.

X-ray crystallographic analysis reveals that the G-actin monomer is separated into two lobes by a deep cleft (Figure 17-5a). At the base of the cleft is the *ATPase fold*, which is the site where ATP and Mg^{2+} are bound. The ATPase fold has structural similarity to the GTP-binding cleft of the GTPase molecular switches (see Figure 15-7). The floor of the cleft in G-actin acts as a hinge that allows the lobes to flex relative to each other. When ATP or ADP is bound to G-actin, the nucleotide affects the conformation of the molecule (in fact, without a bound nucleotide, G-actin denatures very quickly).

FIGURE 17-5 Structures of monomeric G-actin and F-actin filaments. (a) Structure of the actin monomer (measuring $5.5 \times 5.5 \times 3.5\,\mathrm{nm}$), which is divided by a central cleft into two approximately equal-sized lobes and four subdomains, numbered I–IV. ATP (yellow)

binds at the bottom of the cleft and contacts both lobes (the green ball represents Mg^{2+}). The N- and C-termini lie in subdomain I. (b) An actin filament appears as two strands of subunits. One repeating unit consists of 28 subunits (14 in each strand, indicated by * for one strand), covering a distance of 72 nm. The ATP-binding cleft of every actin subunit is oriented toward the same end of the filament. The end of a filament with an exposed binding cleft is the $(-)$ end; the opposite end is the $(+)$ end. (c) In the electron microscope, negatively stained actin filaments appear as long, flexible, and twisted strands of beaded subunits. Because of the twist, the filament appears alternately thinner (7-nm diameter) and thicker (9-nm diameter) (arrows). (The microfilaments visualized in a cell by electron microscopy are F-actin filaments plus any bound proteins.)

[Part (a) Data from C. E. Schutt et al., 1993, *Nature* **365**:810, PDB ID 2btf, courtesy of M. Rozycki.]

G-actin can polymerize, in a reversible reaction, into F-actin. The F-actin filaments that form in vitro are indistinguishable from microfilaments seen in cells, indicating that F-actin is the major component of microfilaments.

From the results of x-ray diffraction studies of actin filaments and from the actin monomer structure shown in Figure 17-5a, scientists have determined that the subunits in an actin filament are arranged in a helical structure (Figure 17-5b). In this arrangement, the filament can be considered as two helical strands wound around each other. Each subunit in the structure contacts one subunit above it and one below it in its own strand as well as two subunits in the other strand. The subunits in a single strand wind around the back of the other strand and repeat after 72 nm, or 14 actin subunits. Since there are two strands, the actin filament appears to repeat every 36 nm (see Figure 17-5b). When F-actin is viewed by electron

microscopy after negative staining with uranyl acetate, it appears as a twisted string whose diameter varies between 7 and 9 nm (Figure 17-5c).

F-Actin Has Structural and Functional Polarity

All subunits in an actin filament are oriented the same way. A consequence of this subunit orientation is that the filament as a whole exhibits polarity; that is, one end of the filament differs from the other. As we will see, a result of this subunit orientation is that one end of the filament is favored for the addition of actin subunits and is designated the (+) end, whereas the other end is favored for removal of subunits and is designated the (−) end. At the (+) end, the ATP-binding cleft of the terminal actin subunit contacts the neighboring subunit, whereas on the (−) end, the cleft is exposed to the surrounding solution (see Figure 17-5b).

The cleft in an actin subunit, and therefore the polarity of a filament, is not detectable without the atomic resolution afforded by x-ray crystallography. However, the polarity of actin filaments can be demonstrated by electron microscopy in so-called decoration experiments, which exploit the ability of the motor protein myosin (discussed in Section 17.5) to bind specifically to actin filaments. In this type of experiment, an excess of myosin S1, a proteolytic

cleavage product of myosin containing the actin-binding head domain (see Figure 17-22), is mixed with actin filaments under conditions where binding takes place. Myosin attaches to the sides of a filament and binds with a slight tilt. When all the actin subunits are bound by myosin, the filament appears as if decorated with arrowheads that all point toward the (−) end of a filament (Figure 17-6). Thus the (−) end is often called the *pointed end* of an actin filament. The (+) end is known as the *barbed end*. Because myosin binds to actin filaments and not to microtubules or intermediate filaments, arrowhead decoration is one criterion by which actin filaments can be definitively identified among the other cytoskeletal fibers in electron micrographs of cells.

EXPERIMENTAL FIGURE 17-6 Myosin S1 decoration demonstrates the identity and polarity of an actin filament. Myosin S1 head domains bind to actin subunits in a particular orientation. When bound to all the subunits in a filament, S1 appears to spiral around the filament. This coating of myosin heads produces a series of arrowhead-like decorations (arrows). The polarity in decoration defines a pointed (−) end and a barbed (+) end.

KEY CONCEPTS OF SECTION 17.1

Microfilaments and Actin Structures

- Microfilaments can be assembled into diverse structures, many of which are associated with the plasma membrane (see Figure 17-4a).
- Actin, the basic building block of microfilaments, is an abundant protein of eukaryotic cells and is highly conserved among species.
- Actin can reversibly assemble into filaments that consist of two helices of actin subunits.
- The actin subunits in a filament are all oriented in the same direction, with the nucleotide-binding site exposed on the $(-)$ end (see Figure 17-5).

17.2 Dynamics of Actin Filaments

The actin cytoskeleton is a dynamic structure, in which the assembly and disassembly of actin filaments, and their association into functional structures, are exquisitely regulated. In some cytoskeletal structures, microfilaments are stable for hours, whereas in others they grow or shrink in seconds. These changes in the organization of actin filaments can generate forces that cause large changes in the shape of a cell or drive movement of intracellular structures. In this section, we first consider actin's intrinsic ability to polymerize and depolymerize and then look at how these processes are modulated by accessory proteins. We will see how actin-binding proteins make important contributions to the stability and regulated disassembly of filaments. In subsequent sections, we turn to the mechanisms that cells use to assemble and organize actin filaments, how the location of assembly within a cell is regulated by signaling pathways, and how together with myosins they can drive motility processes. A summary of the actin-binding proteins discussed in this chapter is presented in Table 17-1.

Table 17-1 • Summary of Actin-Binding Proteins Discussed in This Chapter

Name	Primary Function
Profilin	G-actin nucleotide exchange
Cofilin	F-actin disassembly

Thymosin-β_4	G-actin monomer sequestering
CapZ $(+\text{end})$ and Tropomodulin $(-\text{end})$	F-actin end-binding
Gelsolin	F-actin severing
Formins, Arp2/3	Actin nucleating
Fimbrin, α-actinin, Filamin, Spectrin	F-actin cross-linking
Ankyrin, Band 4.1, ERM proteins, Dystrophin	F-actin-membrane linking
Myosins	F-actin-based molecular motors
Nebulin	F-actin length regulation
Tropomyosin	F-actin stabilizing

Actin Polymerization In Vitro Proceeds in Three Steps

The in vitro polymerization of G-actin monomers to form F-actin filaments can be monitored by viscometry, sedimentation, fluorescence spectroscopy, or fluorescence microscopy (see Chapter 4). When actin filaments grow long enough to become entangled, the viscosity of the solution, which is measured as a decrease in its flow rate in a viscometer, increases. The basis of the sedimentation assay is the ability of ultracentrifugation (100,000*g* for 30 minutes) to sediment F-actin, but not G-actin. The third assay makes use of G-

actin covalently labeled with a fluorescent dye; the fluorescence spectrum of the labeled G-actin monomer changes when it polymerizes into F-actin. Finally, growth of the fluorescently labeled filaments can be imaged in real time with fluorescence microscopy. These four assays are useful for kinetic studies of actin polymerization and for characterizing actin-binding proteins to determine how they affect actin dynamics or how they cross-link actin filaments.

The mechanism of actin assembly has been studied extensively. Remarkably, one can purify G-actin at a high protein concentration without it forming filaments — provided it is maintained in a buffer with ATP and low levels of cations. The addition of cations (e.g., to 100 mM K^+ and 2 mM Mg^{2+}) to a solution of G-actin will induce polymerization into F-actin filaments, with the kinetics of the reaction depending on the starting concentration of G-actin. The process is reversible: F-actin depolymerizes into G-actin when the ionic strength of the solution is lowered. The polymerization of pure G-actin in vitro proceeds in three sequential phases (Figure 17-7a).

FIGURE 17-7 The three phases of in vitro G-actin polymerization. (a) In the initial nucleation phase, ATP–G-actin monomers (red) slowly form stable complexes of actin (purple). These nuclei are rapidly elongated in the second phase by the addition of subunits to both ends of the filament. In the third phase, the ends of actin filaments are in equilibrium with monomeric G-actin. (b) Time course of the in vitro polymerization reaction reveals the initial lag period associated with nucleation, the elongation phase, and the steady state. (c) If some short, stable actin filament fragments are added at the start of the reaction to act as nuclei, elongation proceeds immediately, without any lag period.

1. The *nucleation phase* is marked by a lag period in which G-actin subunits combine into an oligomer of two or three subunits. When the oligomer reaches three subunits in length, it can act as a seed, or nucleus, for the next phase.
2. During the *elongation phase*, the short oligomer rapidly increases in length by the addition of actin monomers to both of its ends. As F-actin filaments grow, the concentration of G-actin monomers decreases until equilibrium is reached

between the filament ends and monomers, and a steady state is reached.

3. In the *steady-state phase*, G-actin monomers exchange with subunits at the filament ends, but there is no net change in the total length of filaments.

The kinetic curves in Figure 17-7b, c show the filament mass during each phase of polymerization. We can show experimentally that the lag period is due to nucleation, because the lag period can be eliminated by the addition of a small number of F-actin nuclei — consisting of very short filaments — to a solution of G-actin (Figure 17-7c).

How much G-actin is required for nucleation to occur? Scientists have placed various concentrations of G-actin under polymerizing conditions and found that, below a certain concentration, filaments cannot assemble (Figure 17-8). Above this concentration, filaments begin to form; when steady state is reached, the incorporation of more free subunits is balanced by the dissociation of subunits from filament ends to yield a mixture of filaments and monomers. The minimal concentration of monomers at which filaments form is known as the **critical concentration (C_c)**. Below C_c, filaments will not form; above C_c, filaments form. At steady state, the concentration of monomeric actin remains at the C_c (Figure 17-8).

FIGURE 17-8 Determination of the critical concentration (C_c) of G-actin above which filaments are formed. When different concentrations of actin are placed under polymerizing conditions and the reaction is allowed to come to steady state, the C_c is the concentration at which actin filaments begin to form. At initial monomer concentrations below the C_c, no polymerization takes place. At monomer concentrations above the C_c, filaments assemble until steady state is reached with the monomer concentration remaining at C_c.

Actin Filaments Grow Faster at (+) Ends than at (−) Ends

Using myosin S1 decoration experiments, we saw earlier that F-actin has an inherent structural polarity that is due to the uniform orientation of subunits in the filament (see Figures 17-5 and 17-6). As we described above, G-actin can bind ATP or ADP. When ATP–G-actin assembles into a filament, the ATP is rapidly hydrolyzed to ADP-P_i–actin, and then the P_i is more slowly released, generating a

filament mostly composed of ADP-P_i–actin and ADP-actin. Moreover, this gives rise to two different ends: the (+) end is composed of ATP-actin or ADP-P_i–actin, whereas the (−) end has ADP–G-actin. If free ATP–G-actin is added to such a preexisting myosin-decorated filament, the two ends grow at very different rates (Figure 17-9). In fact, the rate of addition of ATP–G-actin is nearly 10 times faster at the (+) end than at the (−) end. Kinetic experiments have shown that the rate of addition is about $12\,\mu M^{-1}\,s^{-1}$ at the (+) end and about $1.3\,\mu M^{-1}\,s^{-1}$ at the (−) end (Figure 17-10a). This means that if 1 μM of free ATP–G-actin is added to preformed filaments, 12 subunits, on average, will be added to the (+) end every second, whereas only 1.3 will be added to the (−) end every second. Note that the rate of addition (the association rate) is a function of the concentration of free ATP–G-actin. What about the rate of subunit loss from each end? By contrast with the rates of addition, the rates of dissociation of G-actin subunits from the two ends are quite similar: about $1.4\,s^{-1}$ from the (+) end and $0.8\,s^{-1}$ from the (−) end. Since this dissociation is simply the rate at which subunits leave the filament ends, it does not depend on the concentration of free ATP–G-actin.

Courtesy Thomas Pollard.

EXPERIMENTAL FIGURE 17-9 The two ends of a myosin-decorated actin filament grow at different rates. When short actin filaments are decorated with myosin S1 heads to reveal the orientation of the filaments and then used to nucleate actin polymerization, G-actin monomers are added much more efficiently to the (+) ends than to the (−) ends of the nucleating filaments.

FIGURE 17-10 Actin treadmilling. ATP-actin subunits are added faster at the $(+)$ end than at the $(-)$ end of an actin filament, resulting in a lower critical concentration at the $(+)$ end and treadmilling at steady state. (a) The rate of addition of ATP–G-actin is much faster at the $(+)$ end than at the $(-)$ end, whereas the rate of dissociation of actin is similar at the two ends. This difference results in a lower critical concentration at the $(+)$ end. At steady state, ATP-actin is added preferentially at the $(+)$ end, giving rise to a short region of the filament containing ATP-actin and regions containing $\mathrm{ADP\text{-}P_i\text{–}actin}$ and ADP-actin toward the $(-)$ end. (b) At steady state, ATP–G-actin subunits add preferentially to the $(+)$ end, while ADP–G-actin subunits disassemble from the $(-)$ end, giving rise to treadmilling of subunits. For reference, two actin subunits are colored blue, to highlight that over time subunits appear to move from the plus end toward the minus end within the filament.

How do these association and dissociation rates impact actin dynamics? As we noted above, the association rate depends on the free ATP–G-actin concentration, whereas the dissociation rate does not. Thus when the free ATP–G-actin concentration is high, subunits will be added to the filament ends more quickly than subunits will be lost, so the filament will grow. As the concentration is lowered, a point will be reached where the rate of addition is balanced by the rate of loss, and no net filament growth occurs. Consider just the $(+)$ end for the moment. The free G-actin concentration at which rates of addition and loss are equal is called the *critical concentration for the* $(+)$ *end*, C_c^+. We can calculate C_c^+ by setting the rate of assembly equal to the rate of disassembly. Thus at the critical concentration the rate of assembly is C_c^+ times the measured rate of addition of $12\,\mu\mathrm{M}^{-1}\,\mathrm{s}^{-1}(C_c^+ \times 12\,\mathrm{s}^{-1})$, whereas the rate of disassembly is independent of the free actin concentration, namely, $1.4\,\mathrm{s}^{-1}$. Setting these two rates equal to each other yields $C_c^+ = 1.4\,\mathrm{s}^{-1}/12\,\mu\mathrm{M}^{-1}\,\mathrm{s}^{-1}$,

or $0.12\,\mu\text{M}$, for the $(+)$ end. Above this free ATP–G-actin concentration, subunits are added to the $(+)$ end and net growth occurs, whereas below it, there is a net loss of subunits, and shrinkage occurs.

Now let's consider the $(-)$ end. Because the rate of addition is much lower, $1.3\,\mu\text{M}^{-1}\,\text{s}^{-1}$, yet the rate of dissociation is about the same, $0.8\,\text{s}^{-1}$, we expect the critical concentration C_c^- at the $(-)$ end to be higher than C_c^+. Indeed, as we just did for the $(+)$ end, we can calculate C_c^- to be about $0.8\,\text{s}^{-1}/1.3\,\mu\text{M}^{-1}\,\text{s}^{-1}$, or $0.6\,\mu\text{M}$. Thus at less than $0.6\,\mu\text{M}$ free ATP–G-actin — say, $0.3\,\mu\text{M}$—the $(-)$ end will lose subunits. Notice that at this concentration the $(+)$ end will grow, because $0.3\,\mu\text{M}$ is above C_c^+. Because the critical concentrations for the two ends are different, at steady state the free ATP–G-actin will be intermediate between C_c^+ and C_c^-, so the $(+)$ end will grow and the $(-)$ end will lose subunits. This phenomenon is known as **treadmilling** because particular subunits, such as those shown in blue in Figure 17-10b, appear to move through the filament.

The treadmilling of actin filaments is powered by hydrolysis of ATP. When ATP–G-actin binds to the $(+)$ end of a filament, ATP is hydrolyzed to ADP and P_i. Since the P_i is slowly released from the subunits in the filament, the filament becomes organized into three regions: a short region of ATP-actin subunits at the $(+)$ end, ADP-P_i–actin in the middle of the filament, and, following P_i release,

ADP-actin subunits toward the (−) end (Figure 17-10a). During release of P_i from subunits in a filament, actin undergoes a conformational change that is responsible for the different association and dissociation rates at the two ends. Our analysis relies on a plentiful supply of ATP–G-actin, which, as we will see, turns out to be the case in vivo. Thus actin can use the power generated by hydrolysis of ATP to treadmill, and treadmilling filaments can do work in vivo, as we will see later.

Actin Filament Treadmilling Is Accelerated by Profilin and Cofilin

Actin treadmilling in vivo can occur at rates several times higher than happens with pure actin in vitro under physiological conditions. Why is treadmilling faster in vivo, and how does the cell recharge the ADP-actin dissociating from the (−) end into ATP-actin that adds at the (+) end? The answers involve two actin-binding proteins.

The first of these proteins is *profilin*, a small protein that binds G-actin on the side opposite the nucleotide-binding cleft (see the profilin cycle in Figure 17-11). When profilin binds ADP-actin, it opens the cleft and greatly enhances the loss of ADP. Because [ATP] in the cell is much greater than [ADP], ATP readily binds to G-actin, forming a profilin–ATP-actin complex. This complex cannot bind to

the (−) end because profilin blocks the sites on G-actin for (−) end assembly. However, the profilin–ATP-actin complex can bind efficiently to the (+) end. Once the new actin subunit is bound to the filament, profilin dissociates. Profilin activity does not enhance the treadmilling rate, but it does ensure a constant supply of ATP-actin formed from released ADP-actin. As a consequence, essentially all of the free G-actin in a cell has bound ATP.

FIGURE 17-11 Regulation of filament turnover by actin-binding proteins. Actin-binding proteins regulate the rate of assembly and disassembly of actin filaments as well as the availability of G-actin for polymerization. In the profilin cycle (step 1), profilin binds ADP–G-actin and catalyzes the exchange of ADP for ATP. The profilin–ATP–G-actin complex can deliver actin to the (+) end of a filament with dissociation and recycling of profilin. In the cofilin cycle (step 2), cofilin binds preferentially to regions of filaments containing ADP-actin,

inducing them to fragment and thus enhancing depolymerization by making more filament ends. In the thymosin-β_4 cycle (step **3**), ATP–G-actin made available by the profilin cycle is bound by thymosin-β_4, which sequesters it from polymerization. As the free G-actin concentration is lowered by polymerization, G-actin–thymosin-β_4 dissociates to make free G-actin available for association with profilin and further polymerization.

Profilin has another important property: it can bind proteins with sequences rich in proline residues at the same time it is bound to actin. We will see later how this property can enhance the rate of actin filament assembly.

The second of the actin-binding proteins is **cofilin**, a small protein that binds specifically to ADP-actin subunits within F-actin. Recall from Figure 17-10a, these are the subunits found toward the (−) end of F-actin. Cofilin binds by bridging two actin monomers and inducing a small change in the twist of the filament. This small twist destabilizes the filament between regions with and without cofilin, breaking it into short pieces. By breaking the filament in this way, cofilin generates many more free (−) ends and therefore greatly enhances the net disassembly of the filament (see the cofilin cycle in Figure 17-11). The released ADP-actin subunits are then recharged by profilin and added to the (+) end as described above.

When purified profilin and cofilin are mixed with purified G-actin under conditions where filaments will form, rates of treadmilling in vitro increase more than tenfold compared to treadmilling in the

absence of these two actin-binding proteins. These enhanced levels of in vitro treadmilling are similar to what is seen in vivo.

Thymosin-β_4 Provides a Reservoir of Actin for Polymerization

It has long been known that cells often have a very large pool of G-actin, sometimes constituting as much as half the actin in the cell. Since cellular actin levels can be as high as 100–400 μM, this means that there can be as much as 50–200 μM unpolymerized actin in cells. Since the critical concentration in vitro is about 0.2 μM, why doesn't all this actin polymerize? The answer is, at least in part, due to G-actin sequestering proteins. One of these proteins is **thymosin-β_4**. When thymosin-β_4 binds to ATP–G-actin, it inhibits addition of the actin subunit to either end of a filament. As an example, let's consider human blood platelets. These disk-shaped cell fragments are very abundant, and when they are activated during blood clotting, they undergo a burst of actin assembly. Platelets are rich in actin; they are estimated to have a total concentration of about 550 μM actin, of which about 220 μM is in the unpolymerized form. They also contain about 500 μM thymosin-β_4, which sequesters much of the free actin. However, as in any protein-protein interaction, free actin and free thymosin-β_4 are in a dynamic equilibrium with actin–thymosin-β_4. When some free actin is incorporated into actin filaments, then more actin–thymosin-β_4 will

dissociate, thus maintaining a steady supply of actin subunits available for polymerization (see the thymosin-β_4 cycle in Figure 17-11). Thus thymosin-$\beta_4$behaves as a buffer of unpolymerized actin, making ATP-actin subunits available as they are needed.

Capping Proteins Block Assembly and Disassembly at Actin Filament Ends

Cells further regulate treadmilling and actin filament dynamics with *capping proteins* that bind to filament ends. If this were not the case, actin filaments would continue to grow and disassemble in an uncontrolled manner. As one might expect, two classes of proteins have been discovered: ones that bind the (+) end and ones that bind the (−) end (Figure 17-12).

FIGURE 17-12 Filament capping proteins. Capping proteins block assembly and disassembly at filament ends. CapZ blocks the (+) end, which is where filaments normally grow, so its function is to limit actin dynamics to the (−) end. The capping protein tropomodulin blocks (−) ends, where filament disassembly normally occurs; thus the major function of tropomodulin is to stabilize filaments.

A protein known as **CapZ**, consisting of two closely related subunits, binds with a very high affinity ($\sim 0.1\,\mathrm{nM}$) to the (+) end of an actin filament, thereby inhibiting subunit addition or loss. The concentration of CapZ in cells is generally sufficient to rapidly cap any newly formed (+) ends. So how can filaments grow at their (+) ends? At least two mechanisms regulate the activity of CapZ. First, the capping activity of CapZ is inhibited by the regulatory phospholipid phosphatidylinositol 4,5-bisphosphate [$\mathrm{PI(4,5)P_2}$], found in the plasma membrane (see Chapter 16). Second, recent work has shown that certain regulatory proteins are able to bind the (+) end and protect it from CapZ while still allowing assembly there. Thus cells have evolved an elaborate mechanism to block assembly of actin filaments at their (+) ends except when and where assembly is needed.

Tropomodulin is one of the regulatory proteins that inhibit filament assembly and disassembly by binding to the (−) end of an actin filament. This protein is found predominantly in cells in which actin filaments need to be stabilized for long periods of time, such as the short actin filaments in the cortex of red blood cells and the actin

filaments in muscle. In both of these cells, tropomodulin works with the actin-binding protein tropomyosin to stabilize actin filaments. We will look at these protein interactions in more detail later in this chapter.

In addition to CapZ, another class of proteins can cap the $(+)$ ends of actin filaments. These proteins can also sever actin filaments. One member of this family, *gelsolin*, is regulated by Ca^{2+} ion concentration. On binding Ca^{2+}, gelsolin undergoes a conformational change that allows it to bind to the side of an actin filament and then insert itself between subunits of the helix, thereby breaking the filament. It then remains bound to and caps the $(+)$ end, generating a new $(-)$ end that can disassemble. As we discuss in a later section, actin cross-linking proteins can provide linkages between individual actin filaments to turn a solution of F-actin into a gel. If gelsolin is added to such a gel and the level of Ca^{2+} is elevated, gelsolin will sever the actin filaments and turn the gel back into a liquid solution. This ability to turn a gel into a sol is why the protein was named *gelsolin*.

KEY CONCEPTS OF SECTION 17.2

Dynamics of Actin Filaments

- The rate-limiting step in actin filament assembly is the formation of a short actin oligomer (nucleus) that can then be elongated into filaments.
- The critical concentration (C_c) is the concentration of G-actin below which actin filaments will not form.

- When the concentration of G-actin is above the C_c, the filament end will grow; when it is less than the C_c, the filament will shrink (see Figure 17-8).
- ATP–G-actin is added much faster at the $(+)$ end than at the $(-)$ end, resulting in a lower critical concentration at the $(+)$ end than at the $(-)$ end.
- At steady state, actin subunits treadmill through a filament. Treadmilling means ATP-actin is added at the $(+)$ end, ATP is hydrolyzed to ADP and P_i, P_i is lost slowly, and ADP-actin dissociates from the $(-)$ end.
- The length and rate of turnover of actin filaments is regulated by specialized actin-binding proteins (see Figure 17-11). Profilin enhances the exchange of ADP for ATP on G-actin; cofilin binds regions of ADP–F-actin to break the filament and generate new $(-)$ ends to enhance the rate of disassembly of ADP-actin from filament $(-)$ ends, and thymosin-β_4 binds G-actin to provide reserve G-actin when it is needed. Capping proteins bind to filament ends, blocking assembly and disassembly.

17.3 Mechanisms of Actin Filament Assembly

The rate-limiting step of actin polymerization is the formation of an initial actin nucleus from which a filament can grow (see Figure 17-7a). In cells, this step is used as a control point to determine where actin filaments are assembled and what types of actin structures are generated (see Figures 17-1 and 17-4). Two major classes of *actin-nucleating proteins*, the **formin** protein family and the **Arp2/3 complex**, nucleate actin assembly under the control of signal transduction pathways. Moreover, they nucleate the assembly of different actin structures: formins lead to the assembly of long actin filaments, whereas the Arp2/3 complex leads to branched networks of filaments. Here we discuss each separately and see how the power of actin polymerization can drive motile processes in a cell. We then touch on other specialized actin-nucleating factors.

Formins Assemble Unbranched Filaments

Formins are found in nearly all eukaryotic cells as a diverse family of proteins; seven different classes are present in vertebrates. Although they are diverse, all formin family members have two adjacent domains in common, the so-called FH1 and FH2 domains (formin-homology domains 1 and 2). Two FH2 domains from two

individual formin monomers associate to form a doughnut-shaped complex (Figure 17-13a). This complex has the ability to nucleate actin assembly by binding two actin subunits, holding them so that the (+) end of the nascent filament is toward the FH2 domains. The filament can now grow at the (+) end while the FH2 domain dimer remains attached to it. How is this possible? As we saw earlier, an actin filament can be thought of as two intertwined strands of subunits. The FH2 dimer can bind to the two terminal subunits. It then probably rocks between the two end subunits, letting go of one to allow addition of a new subunit and then binding the newly added subunit and freeing up space for the addition of another subunit to the other strand. In this way, rocking between the two subunits on the end, it can remain attached while simultaneously allowing growth at the (+) end (Figure 17-13a).

FIGURE 17-13 Actin nucleation by the formin FH2 domain. (a) Formins have a domain called *FH2* that can form a dimer and nucleate filament assembly. The dimer binds two actin subunits (step **1**) and, by rocking back and forth (steps **2**–**4**), can allow insertion of additional subunits between the FH2 domain and the (+) end of the growing filament. The FH2 domain protects the (+) end from being capped by capping proteins. (b) The FH2 domain of a formin was labeled with colloidal gold (black dot) and used to nucleate assembly of an actin filament. The resulting filament was visualized by electron microscopy after staining with uranyl acetate. Formins assemble long unbranched filaments.

[Part (b) Republished with permission from AAAS, from D. Pruyne et al., 2002, "Role of Formins in Actin Assembly: Nucleation and Barbed-End Association," *Science* **297**(5581): 612–615; permission conveyed through Copyright Clearance Center, Inc.]

The FH1 domain adjacent to the FH2 domain also makes an important contribution to actin filament growth (Figure 17-14). This domain is rich in proline residues, which serve as sites for the binding of several profilin molecules. We discussed earlier how

profilin can exchange the ADP nucleotide on G-actin for ATP to generate profilin–ATP-actin. The FH1 domain behaves as a landing site for profilin–ATP–G-actin to increase the local concentration of these complexes. The actin from these profilin-actin complexes is then fed into the FH2 domain to add actin to the (+) end of the filament, and the profilin is released (Figure 17-14).

FIGURE 17-14 Regulation of formin activity by an intramolecular interaction. Some of the formin classes found in vertebrates are regulated by an intramolecular interaction. In its inactive state, the formin folds back on itself to inhibit the activity of the FH2 domain. The inactive formin is activated when its Rho-binding domain (RBD) binds to membrane-bound active Rho-GTP, resulting in exposure of the formin's FH2 domain, which can then nucleate the assembly of a new actin filament. All formins have an FH1 domain adjacent to the FH2 domain; the proline-rich FH1 domain is a site for recruitment of profilin–ATP–G-actin complexes that can then be fed into the growing (+) end. For simplicity of representation, a single formin protein is shown, but as shown in Figure 17-13, the FH2 domain functions as a dimer to nucleate actin assembly. Regulation of the Rho family of small GTPases is detailed in Figures 17-40 and 17-42.

Since formin allows rapid addition of actin subunits to the (+) end, long filaments with a formin at their (+) end are generated (Figure 17-13b). Thus formins not only nucleate actin assembly, but they remain bound to the (+) end and, in conjunction with profilin, they facilitate rapid filament assembly. To ensure continued growth of a filament, formins bind to the (+) end in such a way that precludes binding of a (+) end capping protein such as CapZ, which would terminate assembly.

To be useful to a cell, formin activity must be regulated. Many formins exist in a folded, inactive conformation as a result of an interaction between the first half of the protein and its C-terminal tail. These formins are activated by membrane-bound Rho-GTP, a Ras-related small GTPase (discussed in Section 17.7). When Rho switches from its inactive Rho-GDP form to its activated membrane-bound Rho-GTP state, it can bind and activate these formins (see Figure 17-14).

Formins are responsible for the assembly of long actin filaments such as those found in muscle cells, stress fibers, filopodia, and the contractile ring that forms during cytokinesis (see Figure 17-4). The different formin classes in animals differ in their ability to nucleate actin assembly, and some formins can also bundle actin filaments.

The Arp2/3 Complex Nucleates Branched Filament Assembly

The Arp2/3 complex is a protein machine consisting of seven subunits, two of which are *a*ctin-*r*elated *p*roteins (Arp; Figure 17-15a). It is found in essentially all eukaryotes, including plants, yeasts, and animal cells. The Arp2/3 complex alone is a very poor nucleator. To nucleate the assembly of branched actin filaments, Arp2/3 needs to be activated by a **nucleation promoting factor (NPF)**. The major NPF family is characterized by the presence of a region called *WCA* (*W*H2, *c*onnector, *a*cidic for the acidic amino acid residues it contains). Experiments have shown that if the WCA domain is added to an actin assembly assay together with preformed actin filaments, Arp2/3 becomes a potent nucleator of further actin assembly.

FIGURE 17-15 Actin nucleation by the $\mathrm{Arp2/3}$ complex. (a) X-ray crystallographic structure of the $\mathrm{Arp2/3}$ complex, with five of the subunits in gray and the Arp2 and Arp3 subunits in green and blue. (b) To nucleate actin assembly efficiently, $\mathrm{Arp2/3}$ must interact with the activating part of an NPF, shown here with its W (WH2), C (connector), and A (acidic) domains. Step **1** involves binding of an actin subunit to the W domain of each NPF. Two NPF-actin complexes then bind the $\mathrm{Arp2/3}$ complex (step **2**). This interaction induces a conformational change in the $\mathrm{Arp2/3}$ complex. After binding of the $\mathrm{Arp2/3}$ complex to the side of an actin filament, the actin subunits delivered by the W domains bind to the $\mathrm{Arp2/3}$ complex (step **3**), which then initiates the assembly of an actin filament at the available $(+)$ end (step **4**). The $\mathrm{Arp2/3}$ branch makes a characteristic 70° angle between the old and new filaments. (c) Averaged image compiled from several electron micrographs of $\mathrm{Arp2/3}$ at an actin branch. (d) Image of actin filaments in the leading edge of a motile cell, with a magnification and coloring of individual branched filaments.

How do the Arp2/3 complex and NPFs nucleate the assembly of actin filaments? Two NPFs each bind an actin subunit at their WH2 domains, and together, they activate the Arp2/3 complex through its interaction with their connector and acidic domains. In the inactive Arp2/3 complex, the two actin-related polypeptides — Arp2 and Arp3 — are in the wrong configuration to nucleate filament assembly (see Figure 17-15b, step **2**). When activated by the NPFs, Arp2 moves into a new configuration permitting the complex to bind to the side of a preexisting actin filament. The actin subunits brought in by the WH2 domains of the NPFs bind to the Arp2/3 template to nucleate filament assembly at the (+) end (Figure 17-15b, step **3**). The NPFs are released, and the new (+) end then grows as long as ATP–G-actin is available or until it is capped by a (+) end capping protein such as CapZ. The angle between the old filament and the new one is 70° (Figure 17-15b, c). This is also the angle observed experimentally in branched filaments at the leading edges of motile cells, which are believed to be formed by the action of the activated Arp2/3 complex (Figure 17-15d). As we discuss in subsequent sections, the Arp2/3 complex can be used to drive actin polymerization that powers intracellular motility.

Actin nucleation by the Arp2/3 complex is finely controlled, and NPFs are part of that regulatory process. One NPF is called **WASp**, as it is defective in patients with Wiskott-Aldrich syndrome, an X-linked disease characterized by eczema, low platelet count, and immune deficiency. WASp exists in a folded inactive conformation

that makes the WCA domain unavailable (Figure 17-16). To ensure that WASp is activated only at the plasma membrane, its activation requires two signals. One signal is binding between WASp and the regulatory phospholipid $PI(4,5)P_2$,which is characteristically enriched in the plasma membrane (Chapter 16). WASp binds $PI(4,5)P_2$ through its basic domain. The second signal is binding of the activated form of the small GTP-binding protein Cdc42 to the RBD region of WASp. GTP-Cdc42 is itself activated in response to certain signaling pathways (discussed in Section 17.7). This type of two-signal input, called *coincidence detection*, ensures that the protein is activated only at the right place — at the plasma membrane — and by the right signaling pathway. Once bound to the two input signals, the conformation of WASp opens up, and the WCA domain becomes accessible.

FIGURE 17-16 Regulation of the $\mathrm{Arp2/3}$ complex by WASp and PI(4,5)P2. The NPF WASp is inactive due to an intramolecular interaction that masks the WCA domain. It is activated by a coincidence detection mechanism: it must bind both the regulatory phospholipid PI(4,5)P2 though its basic domain (B) and the membrane-bound active small G protein Cdc42-GTP (a member of the Rho family) through its Rho-binding domain (RBD). When activated in this way, the intramolecular interaction in WASp is relieved, allowing the W domain to bind actin and the acidic A domain to activate the $\mathrm{Arp2/3}$ complex. For simplicity, only a single NFP-$\mathrm{Arp2/3}$ interaction is shown. Regulation of the Rho family of small GTPases is detailed in Figures 17-40 and 17-42.

A second NPF is a large protein complex called *WAVE*, which also has a WCA domain that can activate the $\mathrm{Arp2/3}$ complex. WAVE is also activated by coincidence detection, specifically by binding to acidic phospholipids and to the active form of another small GTP-binding protein, Rac1. As we discuss in Section 17.7, activation of the $\mathrm{Arp2/3}$ complex by Cdc42 through WASp and by Rac1 through WAVE induces the formation of different microfilament-based structures.

Although formins and the $\mathrm{Arp2/3}$ complex are found in fungi, plants, and animals, additional actin nucleators have been discovered in animal cells. One of these, called *Spire*, has four tandem WH2 domains, so it can bind four actin monomers. It does this in a manner that allows the actins to assemble into a filament, although the detailed mechanism remains to be understood. Given that actin filaments perform so many functions in cells, it is not

surprising that additional NPF proteins and actin nucleators have recently been described.

Intracellular Movements Can Be Powered by Actin Polymerization

How can actin polymerization be harnessed to do work? As we have seen, actin polymerization involves the hydrolysis of ATP–G-actin to ADP–G-actin, which allows actin filaments to grow preferentially at the (+) end and disassemble at the (−) end. If a collection of actin filaments were to become immobilized in the network of the cytoskeleton and you could bind to and ride on the assembling (+) ends, you would be transported across the cell. This is just what the intracellular bacterial parasite *Listeria monocytogenes* does to get around the cell. The study of *Listeria* motility was, in fact, the way the nucleating activity of the Arp2/3 protein was discovered. As we will see shortly, *Listeria* has hijacked a normal cell motility process for its own purposes.

Listeria is a food-borne bacterial pathogen that causes mild gastrointestinal symptoms in most adults but can be fatal to elderly or immunocompromised individuals. It enters animal cells and divides in the cytoplasm. Its rapid movement around the cell is powered by massive local polymerization of actin to resemble a comet tail (Figure 17-17a), and when it runs into the plasma

membrane, it continues to use the power of actin polymerization to push its way into the adjacent cell. Since the comet tail is embedded in the stationary cytoskeletal matrix of the cell, the bacterium is pushed forward, ahead of the polymerizing actin. Cytosolic factors then disassemble the tail so that actin subunits can be recycled for further polymerization. To do this, *Listeria* needs to direct the assembly of host-cell actin at one end of the bacterium and at the same time confine assembly there so that it efficiently pushes the bacterium forward. How does it do it? *Listeria* has on its surface a protein called *ActA*, which mimics an NPF by having an actin-binding site and an acidic region that efficiently activates the Arp2/3 complex. Researchers have reconstituted *Listeria* motility in the test tube using purified proteins to see what are the minimal requirements for *Listeria* motility. Remarkably, the bacteria will move when just four proteins are added: ATP–G-actin, the Arp2/3 complex, CapZ, and cofilin (see Figure 17-17b, c). We have discussed the role of actin and Arp2/3, but why are CapZ and cofilin needed? As we have seen earlier, CapZ rapidly caps the free (+) end of actin filaments, so when a growing filament no longer contributes to bacterial movement, it is rapidly capped and inhibited from further elongation. In this way, assembly occurs mostly adjacent to the bacterium, where ActA is stimulating the Arp2/3 complex. Cofilin is necessary to accelerate the disassembly of the (−) end region of the actin filament, regenerating free actin to keep the polymerization cycle going (see Figure 17-11). This minimal rate of motility can be increased by the inclusion of VASP and profilin. The ActA protein

binds the host protein VASP, which has three important properties. First, VASP has a proline-rich region that can bind profilin–ATP-actin and thus enhance ATP-actin assembly into the newly formed (+) ends generated by the Arp2/3 complex. Second, it can hold onto the end of the newly formed filament. Third, it can protect the (+) end of the growing filament from capping by CapZ. These properties allow VASP to enhance actin assembly and confine it to the rear of the bacterium.

EXPERIMENTAL FIGURE 17-17 Listeria uses the power of actin polymerization for intracellular movement. (a) Fluorescence microscopy of a cultured cell stained with an antibody to a bacterial surface protein (red) and fluorescent phalloidin to localize F-actin (green). Behind each *Listeria* bacterium is an actin "comet tail" that becomes embedded in the stationary cytoskeletal matrix and so propels the bacterium forward by actin polymerization. When the bacterium runs into the plasma membrane, it pushes the

membrane out into a structure like a filopodium, which protrudes into a neighboring cell. (b) *Listeria* motility can be reconstituted in vitro with bacteria and just four proteins: ATP–G-actin, $\mathrm{Arp2/3}$ complex, CapZ, and cofilin. This phase-contrast micrograph shows bacteria (black), behind which are the phase-dense actin tails. (c) A model of how *Listeria* moves using just four proteins. The ActA protein on the bacterial cell surface activates the $\mathrm{Arp2/3}$ complex to nucleate new filament assembly from preexisting filaments. Filaments grow at their $(+)$ end until capped by CapZ. Actin is recycled through the action of cofilin, which enhances depolymerization at the $(-)$ end of the filaments. In this way, polymerization is confined to the back of the bacterium and propels it forward.

Loisel et al., 1999, "Reconstitution of Actin-Based Motility of *Listeria* and *Shigella* Using Pure Proteins," *Nature* **401**:613–616; permission conveyed through Copyright Clearance Center, Inc.]

To move inside cells, the *Listeria* bacterium hijacks a normal, regulated cellular process involved in cell locomotion. As we discuss in more detail later (Section 17.7), moving cells have a thin sheet of cytoplasm at the front of the cell called the *leading edge* (see Figures 17-1c, 17-4, and 17-15d). This thin sheet of cytoplasm consists of a dense network of actin filaments that are continually elongating at the front of the cell to push the membrane forward. Factors in the leading-edge membrane activate the $\mathrm{Arp2/3}$ complex to nucleate these filaments. Thus the power of actin assembly pushes the membrane forward to contribute to cell locomotion. It is the leading-edge machinery that is co-opted by *Listeria* as it moves within and between host cells.

Microfilaments Function in Endocytosis

As we saw in Chapter 14, endocytosis is the process that cells use to take up particles, molecules, or fluid from the external medium by enclosing them in plasma membrane and then internalizing them. The uptake of molecules or liquid is called *receptor-mediated* or *fluid-phase endocytosis*, and the uptake of large particles is called *phagocytosis* ("cell eating"). Microfilaments participate in both of these processes.

Fluid-phase endocytosis is a multistep process, involving collection of cargo proteins in a clathrin-coated pit, deformation and invagination of the membrane by the clathrin coat, pinching off the membrane by the dynamin GTPase, and movement of the endosome into the cell interior (see Figures 14-20 and 14-29). The power of actin assembly contributes to this process. Endocytosis assembly factors recruit NPFs so that as the endocytic vesicles invaginate and pinch off from the membrane, they are driven into the cytoplasm, powered by a rapid and short-lived burst (a few seconds in duration) of actin polymerization driven by the Arp2/3 complex (Figure 17-18a). Although the physical mechanism that drives the endocytic vesicle into the cytoplasm is not fully resolved, the actin-based machinery is similar to that used in leading-edge formation and *Listeria* motility. This actin-based movement of endocytic vesicles can be reconstituted in vitro (Figure 17-18b).

FIGURE 17-18 $\mathrm{Arp2/3}$-dependent actin assembly during endocytosis. (a) Clathrin-mediated endocytosis is a rapid and ordered process. It has been best studied in yeast, in which the temporal order of specific steps has been delineated. In vivo imaging has shown that endocytosis assembly factors recruit NPFs that activate the $\mathrm{Arp2/3}$ complex. A burst of $\mathrm{Arp2/3}$-dependent actin assembly drives internalization of endocytic vesicles away from the plasma membrane. For clarity, other factors involved in endocytosis, such as clathrin, the adaptin AP2 and dynamin are not shown (see Figure 14-20). (b) Endosome movement can be reconstituted in vitro. Endosomes isolated from cells that had taken up fluorescently labeled transferrin (red) were added to a cell extract containing fluorescently labeled actin (green). The endosomes bind WASp, which then activates the $\mathrm{Arp2/3}$ complex to assemble actin tails that propel them through the cytoplasm.

Phagocytosis by leukocytes (white blood cells) is a vital process in the recognition and removal of pathogens, such as bacteria. The immune system identifies a bacterium as foreign and makes antibodies that recognize surface features of the bacterium. As we discussed in Chapter 3, each antibody has a region called the *Fab domain* that binds specifically to its antigen, in this case a component on the bacterial cell surface. As antibodies coat the

bacterium through interaction between their Fab domains and the cell-surface antigen, a second antibody domain, known as the *Fc domain*, is exposed. This process is known as *opsonization* (Figure 17-19, step **1**; see Chapter 24). Leukocytes have a receptor on their cell surface, called the *Fc receptor*, that binds the Fc portion of the bacterium-bound antibody (step **2**). Initial binding between the leukocyte and opsonized bacterium signals the leukocyte to engulf the bacterium (steps **3** and **4**) inducing assembly of microfilaments at the site of interaction with the bacterium. The assembled microfilaments, together with myosin motor proteins, provide the force necessary to draw the bacterium into the cell, ultimately fully enclosing the pathogen in plasma membrane (step **4**). Once internalized, the newly formed phagosome fuses with lysosomes, and the pathogen is killed and degraded by lysosomal enzymes.

FIGURE 17-19 Phagocytosis and actin dynamics. Actin assembly and contraction drives the phagocytic internalization of particles. Shown here is the phagocytosis and degradation of a bacterium by a leukocyte. An invading bacterium is coated by specific antibodies to a cell-surface protein in a process known as *opsonization* (step 1). The Fc region of the bound antibodies is displayed on the bacterial surface and recognized by a specific receptor, the Fc receptor, on the leukocyte surface (step 2). This interaction signals the cell to assemble a contractile actin structure that results in the internalization and engulfment of the bacterium (step 3). Once it has been internalized into a phagosome, the bacterium is killed and degraded by enzymes delivered from lysosomes (step 4).

Actin assembly has been implicated in other steps of the endocytic pathway as well as in the secretory pathway. For example, an NPF called *WASH* has been implicated in the Arp2/3-dependent nucleation of actin filament on endosomes, regulating their shape and contributing to transport events. Another NPF, called *WHAMM*, localizes to the Golgi complex and is believed to direct the Arp2/3-dependent assembly of actin participating in membrane traffic from the endoplasmic reticulum to the Golgi. The emerging view is that actin assembly facilitates transport between different compartments of the secretory and endocytic pathways.

Toxins That Perturb the Pool of Actin Monomers Are Useful for Studying Actin Dynamics

Certain fungi and sponges produce toxins that target the polymerization cycle of actin and are therefore toxic to animal cells but useful for the study of actin dynamics. Two types of these toxins have been characterized. The first class is represented by two unrelated toxins, cytochalasin D and latrunculin, that promote the depolymerization of filaments, though by different mechanisms. Cytochalasin D, a fungal alkaloid, depolymerizes actin filaments by binding to the (+) end of F-actin, where it blocks further addition of subunits. Latrunculin, a toxin secreted by sponges, binds and sequesters G-actin, inhibiting it from adding to a filament end.

Exposure to either toxin thus increases the monomer pool. When cytochalasin D or latrunculin is added to live cells, the actin cytoskeleton disassembles and cell movements such as locomotion and cytokinesis are inhibited. These observations were among the first to implicate actin filaments in cell motility. Latrunculin is especially useful because it binds actin monomers and prevents any new actin assembly. Thus if latrunculin is added to a cell, the rate at which actin-based structures disappear reflects their normal rate of turnover. This method has revealed that the stability of actin structures varies over a wide range. For example, experiments with latrunculin show that the leading edges of motile cells turn over every 30–180 seconds, and that stress fibers turn over every 5–10 minutes.

In the other class of toxins, the monomer-polymer equilibrium is shifted in the direction of filaments. Examples from this class of toxins are jasplakinolide, another sponge toxin, and phalloidin, which is isolated from *Amanita phalloides* (the "angel of death" mushroom). Jasplakinolide enhances nucleation by binding and stabilizing actin dimers and thereby lowering the critical concentration. Phalloidin binds at the interface between subunits in F-actin, locking adjacent subunits together and preventing actin filaments from depolymerizing. Even when actin is diluted below its critical concentration, phalloidin-stabilized filaments will not depolymerize. Because many actin-based processes depend on actin filament turnover, the introduction of phalloidin into a cell

paralyzes these systems, and the cell dies. Since phalloidin binds only to F-actin, fluorescently labeled phalloidin is commonly used to stain actin filaments for light microscopy (see Figure 17-4).

KEY CONCEPTS OF SECTION 17.3

Mechanisms of Actin Filament Assembly

- Actin assembly is nucleated by two classes of proteins: formins nucleate the assembly of unbranched filaments (see Figure 17-13), whereas the $\mathrm{Arp2/3}$ complex nucleates the assembly of branched actin networks (see Figure 17-15). The activities of formins and $\mathrm{Arp2/3}$ are regulated by signal transduction pathways.
- Functionally different actin-based structures are assembled by formins and by $\mathrm{Arp2/3}$ nucleators. Formins drive the assembly of stress fibers and the contractile ring, whereas $\mathrm{Arp2/3}$ nucleates the assembly of the branched actin filaments found in the leading edge of motile cells.
- The power of actin polymerization can be harnessed to do work, as is seen in the $\mathrm{Arp2/3}$-dependent intracellular movement of pathogenic bacteria (see Figure 17-17) and the inward movement of endocytic vesicles (see Figures 17-18 and 17-19).
- Several toxins affect the dynamics of actin polymerization; some, such as latrunculin, bind and sequester actin monomers, whereas others, such as phalloidin, stabilize filamentous actin. Fluorescently labeled phalloidin is useful for staining actin filaments for their visualization by microscopy.

17.4 Organization of Actin-Based Cellular Structures

We have seen that actin filaments are assembled into a wide variety of different arrangements and that many actin-associated proteins nucleate actin assembly and regulate filament turnover. Dozens of proteins in a vertebrate cell organize these filaments into diverse structures, which the cell uses for an array of functions. In this section, we discuss a few of these proteins, including typical types of actin cross-linking proteins and adapter proteins involved in making links between actin and membrane proteins. One fascinating problem, about which very little is known, is how cells assemble different actin-based structures within the cytoplasm of the same cell. Some of this organization is due to local regulation of actin assembly, a topic we come to at the end of the chapter.

Cross-Linking Proteins Organize Actin Filaments into Bundles or Networks

When actin filaments are assembled in a test tube, they form a tangled network. In cells, however, actin filaments are found in organized structures, such as the highly ordered filament bundles in microvilli or the network characteristic of the leading edge of a motile cell (see Figure 17-4a). These structures are erected with the

help of the filament assembly mechanisms discussed previously and by the presence of **actin cross-linking proteins**.

To be able to organize actin filaments, an actin cross-linking protein must have two F-actin–binding sites (Figure 17-20a). Actin cross-linking proteins can have two actin-binding sites within a single polypeptide, as with *fimbrin*, which builds bundles of filaments all having the same polarity, as seen in the stereocilium (a giant microvillus) in Figure 17-20b. Like fimbrin, *filamin* has dual actin-binding sites in a single polypeptide, but unlike fimbrin, which is short and stiff, filamin has a flexible region between the binding sites that functions like a molecular leaf spring. This enables filamin to form stabilizing cross-links between filaments in a network, such as the ones found in the leading edge of a motile cell.

FIGURE 17-20 Actin cross-linking proteins. Actin cross-linking proteins mold F-actin filaments into diverse structures. (a) Examples of four F-actin cross-linking proteins, all of which have two domains (blue) that bind F-actin. Some have a Ca^{2+}-binding site (purple) that inhibits their activity at high levels of free Ca^{2+}. (b) Transmission electron micrograph of a thin section of a stereocilium (an unfortunate name, since it is really a giant microvillus) on a sensory hair cell in the inner ear. This structure contains a bundle of actin filaments cross-linked by fimbrin, a small cross-linking protein that allows for close and regular interaction of actin filaments. (c) Super-resolution image of the repeating structure of actin

(green) and spectrin (magenta) that form a cagelike network to support the plasma membrane of an axon.

[Part (b) L. G. Tilney et al., 1983, *J. Cell Biol.* **96**(3):822–834; https://doi.org/10.1083/jcb.96.3.822. Part (c) Courtesy of Xiaowei Zhuang and Ke Xu.]

Other actin cross-linking proteins possess a single actin-binding site per polypeptide chain, but the functional protein is a dimer. These dimeric cross-linking proteins assemble to generate a rigid rod with a binding site at either end, as happens with *α-actinin*. Like fimbrin, α-actinin bundles parallel actin filaments, but keeps them farther apart than fimbrin. Another protein, called *spectrin*, is a tetramer with two polypeptide chains containing actin-binding sites and two chains that extend the length of the cross-linking protein. Spectrin spans a much greater distance between actin filaments than does fimbrin or α-actinin. Spectrin assists in forming microfilament networks beneath the plasma membrane (shown in Figure 17-20c and discussed in the next section). The Arp2/3 complex (which we discussed in terms of its ability to nucleate actin filament assembly) is also an important cross-linking protein, attaching the (−) end of one filament to the side of another filament (see Figure 17-15).

Adapter Proteins Link Actin Filaments to Membranes

Actin-based structures are not useful to a cell unless they are attached to specific components by *adapter proteins*. In this section, we describe how adapter proteins attach microfilaments to membranes to provide mechanical support, or attach a contractile apparatus to the membrane. While we discuss some specific examples, essentially all eukaryotic cells have actin-based filaments associated with the plasma membrane as part of a structure known as the *cell cortex*. In these various roles, actin filaments can interact with membranes either laterally or at their ends.

Our first example of actin filaments attached to a membrane involves the human erythrocyte — the red blood cell. The erythrocyte consists essentially of a plasma membrane enclosing a high concentration of the protein hemoglobin. It transports oxygen from the lungs to tissues and brings carbon dioxide from tissues back to the lungs. Erythrocytes must be able to survive the raging torrents of blood flow in the heart, then flow down arteries and survive squeezing through narrow capillaries before being cycled past the lungs and back to the heart. To survive this grueling journey for thousands of cycles, an erythrocyte has an actin-based network underlying the plasma membrane that gives the cell both the tensile strength and the flexibility necessary for its journey. This network is made of short actin filaments about 14 subunits in length, stabilized on their sides by tropomyosin (discussed in more detail in Section 17.6) and by the capping protein tropomodulin on the (−) end. These short filaments serve as hubs for binding about four to six

flexible spectrin molecules, generating a fishnet-like structure (Figure 17-21a) that provides strength and flexibility to the cell cortex. Spectrin molecules are attached to membrane proteins in two ways. One is via the protein *ankyrin*, which binds about halfway along a spectrin molecule and also binds to the transmembrane bicarbonate transporter (also known as *band 3*). The other adapter is *band 4.1*, which binds F-actin, the actin-binding domain of spectrin, and *glycophorin C*, another transmembrane protein (Figure 17-21b). Spectrin-based networks, similar to the one found in erythrocytes, occur in many types of cells. For example, an ankyrin-spectrin attachment links the Na^+/K^+ ATPase to the actin cytoskeleton on the basolateral membrane of epithelial cells, and an ordered repeating actin/spectrin network supports the axonal plasma membrane of neurons (Figure 17-20c).

FIGURE 17-21 Lateral attachment of microfilaments to membranes. (a) Electron micrograph of the erythrocyte membrane showing the spoke-and-hub organization of the cortical cytoskeleton supporting the plasma membrane in human erythrocytes. The long spokes are composed mainly of spectrin and can be seen to intersect at the hubs, or membrane-attachment sites. The darker spots along the spokes are ankyrin molecules, which link spectrin to integral membrane proteins. (b) Diagram of the erythrocyte cytoskeleton, showing the two main types of membrane attachments: step **1** through ankyrin to band 3 and step **2** through band 4.1 to glycophorin C. (c) Actin is incorporated into the tips of stereocilia (giant microvilli). Cells with stereocilia were transfected to express GFP-labeled actin for a short period of time and then counterstained with rhodamine-phalloidin to stain all the F-actin. The experiment shows that new actin is incorporated at the tips of the stereocilia. (d) Ezrin, a member of the ezrin-radixin-moesin (ERM) family, links actin filaments laterally to the plasma membrane in surface structures such as microvilli;

attachment can be direct or indirect. Ezrin exists in an inactive, closed cytosolic form. Activation to an open form is mediated by phosphorylation and requires both the presence of the plasma membrane lipid PI(4,5)P2 and a specific ezrin kinase. Ezrin, activated by phosphorylation (P), links directly to the cytoplasmic region of transmembrane proteins (*right*) or indirectly through a scaffolding protein such as EBP50 (*left*). (e) Dystrophin, which has an actin-binding site on its N-terminal end and a C-terminal domain, binds the membrane protein dystroglycan, which itself associates with the extracellular matrix. See Figure 20-41 for more detail.

[Part (a) From T. J. Byers and D. Branton, 1985, *Proc. Nat'l. Acad Sci. USA* **82**:6153; courtesy Daniel Branton. Part (c) A. K. Rzadzinska et al., 2004, *J. Cell Biol.* **164**(6):887–897; https://doi.org/10.1083/jcb.200310055.]

Genetic defects in proteins of the red blood cell cytoskeleton can result in cells that rupture easily, giving rise to diseases known as *hereditary spherocytic anemias* (*spherocytic* because the cells are rounder, *anemias* because there is a shortage of red blood cells) and hence a shorter life span. In human patients, mutations in spectrin, band 4.1, and ankyrin can cause these diseases. ■

Microfilaments also support cell-surface structures such as microvilli and membrane ruffles. If we look at a microvillus, it is clear that its actin filaments must have an end-on attachment at the tip and lateral attachments down its length. What is the orientation of actin filaments in microvilli? Decoration experiments show that the (+) end is at the tip. Moreover, when fluorescent actin is added to a cell, it is incorporated at the tip of a microvillus, showing not only that the (+) end is there, but also that actin filament assembly occurs there (Figure 17-21c). It is not yet known how actin filaments

are attached at the microvillus tip or how assembly is regulated there. This (+) end orientation of actin filaments with respect to the plasma membrane is found almost universally — not just in microvilli, but also, for example, in the leading edges of motile cells. The lateral attachments to the plasma membrane are provided, at least in part, by the *ERM (ezrin-radixin-moesin) family* of proteins. This family consists of regulated proteins that exist in a folded, inactive form. They are activated after being phosphorylated by a specific kinase in a reaction requiring the plasma membrane-localized regulatory phospholipid phosphatidylinositol 4,5-bisphosphate [$PI(4,5)P_2$]. The F-actin–binding and membrane protein–binding sites of the ERM protein are exposed to provide a lateral linkage between membrane and actin filaments (Figure 17-21d). This type of coincident-detection mechanism — requiring both a regulatory lipid and localized kinase — ensures that ERM proteins are only activated at appropriate locations. ERM proteins can link actin filaments to the cytoplasmic domain of membrane proteins directly or indirectly through scaffolding proteins (see Figure 17-21d).

The types of actin-membrane linkages we have discussed so far do not involve areas of the plasma membrane attached directly to other cells in a tissue or to the extracellular matrix, but such linkages do exist. Contact between epithelial cells is mediated by highly specialized regions of the plasma membrane called *adherens junctions* (see Figure 17-1b). Other specialized regions of association

called *focal adhesions* mediate attachment of cells to the extracellular matrix. In turn, these specialized attachments connect to the cytoskeleton, as will be described in more detail when we discuss cell migration (Section 17.7) and cells in the context of tissues (see Chapter 20).

Muscular dystrophies are genetic diseases that are often characterized by the progressive weakening of skeletal muscle. One of these genetic diseases, Duchenne muscular dystrophy, affects the protein dystrophin, whose gene is located on the X chromosome, so the disease is much more prevalent in males than in females. *Dystrophin* is a modular protein whose function is to link the cortical actin network of muscle cells to a complex of membrane proteins that link to the extracellular matrix. Thus dystrophin has an N-terminal actin-binding domain, followed by a series of spectrin-like repeats, and terminates in a domain that binds the transmembrane dystroglycan complex to the extracellular matrix protein laminin (see Figure 17-21d, e and for more detail Figure 20-41). In the absence of dystrophin, the plasma membrane of muscle cells becomes weakened by cycles of muscle contraction and eventually ruptures, resulting in death of the muscle fibers. ■

KEY CONCEPTS OF SECTION 17.4

Organization of Actin-Based Cellular Structures

- Actin filaments are organized by cross-linking proteins that have two F-actin–binding sites. Actin cross-linking proteins can be long or short, rigid or flexible (see Figure 17-20).
- Actin filaments are attached to the plasma membrane by adapter proteins, as seen in erythrocytes and in cell-surface structures such as microvilli (see Figure 17-21).
- Attachment to the plasma membrane can be regulated, as seen in the activation of ERM proteins by phosphorylation.
- Hereditary diseases, such as spherocytic anemias and muscular dystrophy, have been traced to defects in the attachment of the microfilament-based cortical cytoskeleton to the plasma membrane.

17.5 Myosins: Actin-Based Motor Proteins

In Section 17.3, we discussed how actin polymerization nucleated by the Arp2/3 complex can be harnessed to do work, such as moving vesicles during endocytosis, moving cells along a substrate at their leading edges, and propelling a *Listeria* bacterium through the cytoplasm of a host cell. In addition to this actin polymerization–based motility, cells have a large family of motor proteins called **myosins** that can perform work by moving along actin filaments.

The first myosin discovered, *myosin II*, was isolated from skeletal muscle. For a long time, biologists thought that this was the only type of myosin found in nature. However, they then discovered other types of myosins and began to ask how many functional classes might exist. Today we know that there are multiple families of myosins, in addition to the myosin II of skeletal muscle, that move along actin. Indeed, with the discovery and analysis of all these microfilament-based motors and the corresponding microtubule-based motors described in the next chapter, our former relatively static view of cells has been replaced with the realization that the cytoplasm is incredibly dynamic — like a busy freeway system with motors busily ferrying components around.

Myosins have the amazing ability to convert the energy released by ATP hydrolysis into mechanical work (movement along actin). While

all myosins convert the chemical energy of ATP hydrolysis into mechanical work, different myosins perform very different cellular functions. For example, many molecules of myosin II pull together on actin filaments to bring about muscle contraction, whereas myosin V binds to cargo-filled vesicles and transports them along actin filaments. Other types of myosin move organelles around cells or aid in cell motility.

To begin to understand myosins, we first discuss their general structure. Next we explore the diversity of myosin classes and describe in more detail some of those that are common in eukaryotes. We investigate the mechanism that converts the energy released by ATP hydrolysis into work and then see how this mechanism is modified to tailor the properties of specific myosin classes to their specific functions.

Myosins Have Head, Neck, and Tail Domains with Distinct Functions

Much of what we know about myosins comes from studies of myosin II isolated from skeletal muscle. In skeletal muscle, hundreds of individual myosin II molecules are assembled into bipolar bundles called *thick filaments* (Figure 17-22a). In a later section, we will discuss how these myosin filaments interdigitate with actin

filaments to bring about muscle contraction. Here we investigate the properties of the myosin molecule itself.

FIGURE 17-22 Structure of myosin II. (a) Organization of myosin II in filaments isolated from skeletal muscle. Myosin II assembles into bipolar filaments in which the tails form the shaft of the filament and the heads are exposed at the ends. Treatment of bipolar filaments with high salt concentrations and ATP disassembles the filament into individual myosin II molecules. (b) A myosin II molecule consists of two identical heavy chains (light blue) and four light chains (green and dark blue). The tails of the heavy chains form a coiled coil to dimerize; the neck region of each heavy chain has two light chains associated with it. Limited proteolytic cleavage of myosin II generates tail fragments — LMM and S2 — and the S1 motor domain. (c) Three-dimensional model of a single S1 head domain shows that it has a curved, elongated shape and is bisected by a cleft. The nucleotide-binding pocket lies on one side of this cleft, and the actin-binding site lies on the other side near the tip of the head. Wrapped around the shaft of the α-helical neck are two light chains. These chains

stiffen the neck so that it can act as a lever arm for the head. Shown here is the ADP-bound conformation.

[Part (c) Data from S. Gourinath et al., 2003, *Structure* **11**:1621–1627, PDB ID 1qvi.]

Dissolving the myosin thick filament in a solution of ATP and a high concentration of salt generates a pool of individual myosin II molecules. The soluble myosin II molecule is actually a protein complex consisting of six polypeptide subunits. Two of the subunits are identical high-molecular-weight polypeptides known as *myosin heavy chains*. Each consists of a globular *head* domain and a long *tail* domain, connected by a flexible *neck* domain. The tails of the two myosin heavy chains intertwine, so that the head regions are in close proximity. The remaining four subunits of the myosin complex are smaller in size and are known as the *light chains*. There are two types of light chains: the *essential light chain* and the *regulatory light chain*. One light chain of each type associates with the neck region of each heavy chain (Figure 17-22b, *top*). The myosin heavy chain and the two types of light chains are encoded by three different genes.

The soluble myosin II molecule has ATPase activity, reflecting its ability to power movements by hydrolysis of ATP, but which part of the myosin complex is responsible for this activity? A standard approach to identifying functional domains in a protein is to cleave the protein into fragments with specific proteases and then ask which fragments have the activity. Soluble myosin II can be cleaved

by gentle treatment with the protease chymotrypsin to yield two fragments, one called *heavy meromyosin* (*HMM*; *mero* means "part of") and the other, *light meromyosin (LMM)* (Figure 17-22b, *middle*). The heavy meromyosin can be further cleaved by the protease papain to yield subfragment 1 (S1) and subfragment 2 (S2) (Figure 17-22b, *bottom*). By analyzing the properties of the various fragments — S1, S2, and LMM — it was found that the intrinsic ATPase activity of myosin resides in the S1 fragment, as does its F-actin–binding site. Moreover, it was found that the ATPase activity of the S1 fragment is greatly enhanced by the presence of filamentous actin, so that fragment is said to have an *actin-activated ATPase activity*, which is a hallmark of all myosins. The S1 fragment of myosin II consists of the head and neck domains with associated light chains, whereas the S2 and LMM regions make up the tail domain.

X-ray crystallographic analysis of the head and neck domains has revealed the shapes of the subunits, the positions of the light chains, and the locations of the ATP-binding and actin-binding sites (Figure 17-22c). At the base of the myosin head is the α-helical neck, where two light-chain molecules wrap around the heavy chain like C-clamps. In this position, the light chains stiffen the neck region. The actin-binding site is an exposed region at the tip of the head domain. The ATP-binding site is also in the head domain, within a cleft opposite the actin-binding site.

How much of the myosin II molecule is necessary and sufficient for its motor activity? To answer this question, one needs a simple in vitro motility assay. In one such assay, the *sliding-filament assay*, myosin molecules are tethered to a coverslip to which is added stabilized, fluorescently labeled actin filaments and ATP. Because the myosin molecules are tethered, they cannot slide; thus any force generated by the interaction of myosin heads with actin filaments forces the filaments to move relative to the myosin. The tethered myosin molecules or fragments pull toward the (+) end of a filament, so the force that myosin generates causes the filaments to move with the (−) end leading (Figure 17-23). Using the sliding-filament assay, one can show that the S1 fragment of myosin II is sufficient to move actin filaments (Figure 17-23a). The rate at which myosin moves an actin filament can be determined from video recordings of sliding-filament assays (Figure 17-23b).

EXPERIMENTAL FIGURE 17-23 The sliding-filament assay is used to detect myosin-powered movement. (a) After myosin S1 fragments are adsorbed onto the surface of a glass coverslip, excess unbound myosin is removed; the coverslip is then placed myosin-side-down on a glass slide to form a chamber through which solutions can flow. A solution of actin filaments, made visible and stable by staining with rhodamine-labeled phalloidin, is allowed to flow into the chamber. In the presence of ATP, the myosin heads pulls toward the (+) ends of the actin filaments by the mechanism discussed later and illustrated in Figure 17-26. Because the myosin tails are immobilized, movement of the heads toward the (+) ends causes sliding of the filaments, which appear to be moving with their (–) ends leading the way. (b) Movement of individual filaments can be observed in a fluorescence light microscope. These photographs show the positions of three actin filaments (numbered 1, 2, 3) at 30-second intervals recorded by video microscopy. The rate of filament movement can be determined from such recordings.

All myosins have a domain related to the S1 domain of myosin II, which in all cases is responsible for the motor activity. As we will see in a later section, the length of the neck domain and the numbers and types of light chains associated with it vary among myosin classes. The tail domain does not contribute to motility, but rather defines what is moved by the S1-related domain. Thus as might be expected, tail domains differ among myosins and are tailored to bind specific cargoes.

Myosins Make Up a Large Family of Mechanochemical Motor Proteins

Myosin S1 domains share considerable similarity in their primary amino acid sequence, so it is possible to determine how many myosin genes and how many different classes of myosins exist in the sequenced genome of an organism. For example, there are about 40 myosin genes in the human genome (Figure 17-24), 9 in *Drosophila*, and 5 in budding yeast. Bioinformatic analysis of the sequence relationships among myosin head domains indicates that about 20 distinct classes of myosins have evolved in eukaryotes. As shown in Figure 17-24, the genetic bases for some conditions have been traced to mutations in genes encoding myosins.

FIGURE 17-24 The myosin superfamily in humans. Results of a computer analysis of the relatedness of the S1 head domains of all of the approximately 40 myosins encoded by the human genome. Each myosin is indicated by a blue dot. The lengths of the black lines indicate phylogenetic distance relationships: myosins connected by short lines are closely related, whereas those separated by longer lines are more distantly related. Among these myosins, three classes — myosins I, II, and V — are widely represented among eukaryotes; others have more specialized functions. Indicated are examples in which loss of a specific myosin causes a disease.

[Data from R. E. Cheney, 2001, *Mol. Biol. Cell* **12**:780.]

All myosin head domains use the same mechanism to convert ATP hydrolysis into mechanical work. However, as we will see, subtle variations in this mechanism can have profound effects on the functional properties of different myosin classes. How do these different classes relate with respect to their tail domains? If one uses the protein sequences of myosin tail domains to place the myosins into classes, the myosins fall into the same groupings found when comparing the motor domains. This implies that head domains with specific properties have coevolved with specific classes of tail domains, which makes a lot of sense, and further suggests that each class of myosin has evolved to carry out a specific function.

Among the myosins are three especially well-studied families, commonly found in animals and fungi: the *myosin I*, *myosin II*, and *myosin V* families (Figure 17-25). In humans, 8 genes encode heavy chains for the myosin I family, 14 for the myosin II family, and 3 for the myosin V family (see Figure 17-24).

FIGURE 17-25 Three common classes of myosins. Myosin I molecules consist of a head domain and a neck domain; a variable number of light chains is associated with the neck domain. Members of the myosin I class are the only myosins to have a single head domain. Some of these myosins are believed to associate directly with membranes through lipid interactions. Myosin II molecules have two head domains and two light chains per neck and are the only class that can assemble into bipolar filaments. Myosin V molecules have two head domains and six light chains per neck. They bind specific receptors (brown box) on organelles, which they transport. All myosins in these three classes move toward the (+) end of actin filaments.

The large myosin I family has a variable number of light chains associated with the neck region and is the only type of myosin that has a single heavy chain and so functions with a single head. Only a few of the functions of myosin I molecules have been determined. These include connecting actin filaments to membranes and assisting in endocytosis. Since these myosin molecules have only one head each, several of them must work together to generate movement, and at least one must always be attached to an actin filament during the work cycle.

All myosin II members have a relatively short neck domain and have two light chains per heavy chain. The myosin II class is the only one that assembles into bipolar filaments. Myosin II molecules form bipolar filaments in which the tail domains assemble together into thick bundles with a cluster of head domains at each end. This organization is important for its involvement in contraction; indeed, this is the only class of myosins involved in contractile functions. The large number of members in this class reflects the need for

myosin II filaments with slightly different contractile properties seen in different muscles (e.g., skeletal, cardiac, and various types of smooth muscle) as well as in nonmuscle cells.

Members of the myosin V class have two heavy chains, resulting in a motor with two heads, long neck regions with six light chains each, and tail regions that dimerize and terminate in domains that bind to specific organelles to be transported.

In every case that has been tested so far, myosins move toward the (+) end of an actin filament — with one exception: *myosin VI* found in animals. This unusual myosin has an inserted amino acid sequence in its head domain that causes myosin and its cargo to move toward the (−) end of the actin filament. Myosin VI is believed to move endocytic vesicles along actin filaments away from the plasma membrane. Recall that membrane-associated actin filaments have their (+) ends toward the membrane, so a motor directed toward the (−) end would take carry vesicles away from the membrane toward the center of the cell.

Conformational Changes in the Myosin Head Couple ATP Hydrolysis to Movement

Studies of muscle contraction provided the first evidence that myosin heads slide or walk along actin filaments. Unraveling the mechanism of muscle contraction was greatly aided by the development of in vitro motility assays and single-molecule force measurements. On the basis of information obtained with these two techniques plus the three-dimensional structure of the myosin head (see Figure 17-22c), researchers have developed a model for how myosin harnesses the energy released by ATP hydrolysis to move along an actin filament (Figure 17-26). Because all myosins are thought to use the same basic mechanism to generate movement, we will ignore for the moment whether the myosin tail is bound to a vesicle or is part of a thick filament, as it is in muscle. The most important aspect of this model is that the hydrolysis of a single ATP molecule is coupled to each step taken by a myosin molecule along an actin filament.

FIGURE 17-26 ATP-driven myosin movement along actin filaments. (a) When ADP is bound to the myosin head, it is firmly attached to the actin filament. Step **1**: On exchanging ATP for ADP, the myosin head releases from the actin filament. Step **2**: The head hydrolyzes the ATP to ADP and P_i, which induces a rotation in the head with respect to the neck. This "cocked" state stores the energy released by ATP hydrolysis as elastic energy, like a stretched spring. Step **3**: Myosin in the cocked state is stable until it binds actin. Step **4**: When it encounters actin, the myosin head couples release of P_i with release of the elastic energy to move the actin filament. This movement is known as the *power stroke*, as it

involves moving the actin filament with respect to the end of the myosin neck domain. In the presence of bound ADP, the head remains tightly bound to the actin filament in a state known as *rigor* and is the basis for the unmistakable sign of death, rigor mortis. Step **5**: When ADP is replaced by fresh ATP the head releases from the filament. See R. D. Vale and R. A. Milligan, 2002, *Science* **288**:88. (b) Molecular models of the conformational changes in the myosin head involved in "cocking" the head (*upper panel*) and after the power stroke (*lower panel*). The myosin light chains are shown in dark blue and green; the rest of the myosin head and neck are colored light blue, and actin is red. See S. Fischer et al., 2005, *Proc. Nat'l Acad. Sci. USA* **102**:6873–6876.

[Part (b) Data from Ken Holmes.]

How does myosin convert the chemical energy released by ATP hydrolysis into mechanical work? The S1 head of myosin is an ATPase. When it has ADP bound, the head of myosin binds very tightly to F-actin (Figure 17-26a). When the ADP in the head is exchanged for ATP, its affinity for F-actin is greatly reduced, and it releases from actin (Figure 17-26a, step **1**). Next the myosin head hydrolyzes the ATP, and the hydrolysis products, ADP and P_i, remain bound to it (step **2**). The energy from the hydrolysis of ATP induces a conformational change in the head that results in the head domain rotating with respect to the neck domain, assuming what is known as the "cocked" position (Figure 17-26b, *top*). Next the head binds F-actin tightly (step **3**), inducing both release of P_i and rotation of the head back to its original position, thus moving the actin filament relative to the neck domain (Figure 17-26a, step **4**, and 17-26b, *bottom*). In this way, binding to F-actin induces the movement of the head and the release of P_i, thereby coupling the two processes. This step is known as the **power stroke**. The head remains bound until

the ADP leaves and a fresh ATP binds the head, releasing it from the actin filament (step **5**). The cycle repeats.

How is hydrolysis of ATP in the nucleotide-binding pocket of the head converted into a mechanical force? Hydrolysis of ATP induces a small conformational change in the head domain. This small movement is amplified by a converter region at the base of the head, which acts like a fulcrum causing the rodlike neck (also known as the *lever arm*) to rotate. The rotation is amplified by the neck domain, so the actin filament moves by a few nanometers (see Figure 17-26b).

This model makes a strong prediction: the distance a myosin moves along actin during hydrolysis of one ATP — the myosin **step size** — should be proportional to the length of the neck domain. To test this prediction, mutant myosin molecules were constructed with neck domains of different lengths, and the rate they moved down an actin filament was determined. As the myosins with different neck domains step at the same rate, the rate of movement reflects the step size. As predicted, there was an excellent correlation between the length of the neck domain and the rate of movement (Figure 17-27).

EXPERIMENTAL FIGURE 17-27 The length of the myosin II neck domain determines the rate of movement. To test the lever-arm model of myosin movement, investigators used recombinant DNA techniques to make myosin heads attached to neck domains with increasing numbers of light-chain-binding sites and hence lengths. The rate at which these myosins moved on actin filaments was determined, which reflects the myosin step size. The longer the lever arm, the faster the myosin moved, supporting the proposed mechanism.

[Data from K. A. Ruppel and J. A. Spudich, 1996, *Ann. Rev. Cell Dev. Biol.* **12**:543–573.]

Myosin Heads Take Discrete Steps Along Actin Filaments

The defining property of a myosin is its ability to generate a force when it contacts an actin filament, but the details of this interaction are tailored to the function of the myosin. Researchers have measured the distance a single myosin II head moves a filament and the force generated. The results show that myosin II takes discrete steps, which average out to about 8 nm, and generates 3–5 piconewtons (pN) of force, approximately the same force as that exerted by gravity on a single bacterium. Moreover, myosin II does not interact with the actin filament continuously but rather binds, moves, and releases it. In fact, myosin II spends on average only about 10 percent of each ATPase cycle in contact with F-actin — it is said to have a **duty ratio** of 10 percent. This observation will be important later when we consider that in contracting muscle, hundreds of myosin heads pull on actin filaments, so that at any one time, 10 percent of the heads are engaged to provide a smooth contraction.

Now let us examine how myosin V moves. Recall that myosin V has a much longer neck region than does myosin II (see Figure 17-25). In one set of experiments, scientists added a fluorescent label to one of the two neck domains in myosin V molecules (see Section 4.2 for how this can be achieved). Mixing labeled myosin V molecules with F-actin and ATP, the movement of myosin V was observed using fluorescence microscopy (Figure 17-28a). The labeled head took many 72-nm steps without releasing from the actin — so it is said to move *processively* (Figure 17-28b). In a filament, actin subunits are

oriented to present a myosin-binding site every 36 nm (see Figures 17-5b and 17-28a), so each head binds to every other site along a filament. As the myosin has two heads, each alternately takes 72-nm steps — like someone walking on stepping stones across a river and placing each foot on every other stone. When the label was attached to the tail instead of the neck, the myosin V motor as a whole moved in 36-nm steps. Thus while the step size for each individual head is 72 nm, cargo attached to the myosin V tail region moves in 36-nm steps as a head moves from behind the cargo to in front of it (Figure 17-28a).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 17-28 Myosin V has a step size of 36 nm, with each head stepping hand-over-hand in 72-nm steps. (a) Diagram of how the myosin V heads interact with binding sites spaced 36 nm along an actin filament, with a fluorescent label on the neck domains of one myosin head. While each myosin V head steps "hand-over-hand" down an actin filament in 72-nm steps, the cargo, and hence the motor as a whole, moves in 36-nm steps. (b) A trace of the label on one myosin V neck domain as the molecule walks down an actin

filament. The labeled myosin head takes successive 72-nm steps. As can be seen from the trace, myosin V takes many successive steps along a filament, so it is said to be processive. As shown in panel (a), the step size corresponds to equivalent sites on the helical structure of the actin filament.

[Data from A. Yildiz et al., 2003, *Science* **300**:2061.]

Presumably, myosin V has evolved a long neck domain to take steps that match the distance between myosin-binding sites. Moreover, its ATPase cycle has a high duty ratio of >70 percent. (Compare this with the 10 percent duty ratio of myosin II.) Myosin V has a high duty ratio because its rate of ADP release is quite slow; thus the head remains in contact with the actin filament for a much larger percentage of the cycle. Since a single myosin V molecule has two heads, a duty ratio greater than 50 percent ensures that at least one head is always in contact with actin as it moves down an actin filament. This keeps myosin V and its cargo from falling off. These are exactly the properties one would expect for a motor designed to transport cargo along an actin filament.

KEY CONCEPTS OF SECTION 17.5

Myosins: Actin-Based Motor Proteins

- Myosins are actin-based motors powered by ATP hydrolysis.
- Myosins have a motor head domain, a lever-arm neck domain, and a cargo-binding tail domain (see Figure 17-22).
- There are many classes of myosins, three of which are present in many eukaryotes: myosin I, which has a single head domain; myosin II, which has two heads and assembles into bipolar filaments; and myosin V, which has two heads but does not assemble into filaments (see Figure 17-25).

- Myosins convert ATP hydrolysis to mechanical work by amplifying a small conformational change in the head through the neck domain when the head is bound to F-actin (see Figure 17-26).
- Myosin heads take discrete steps along an actin filament, which can be small (8 nm) and nonprocessive in the case of myosin II or large (36 nm for the motor overall, 72 nm for each head) and processive for myosin V.

17.6 Myosin-Powered Movements

In the previous section, we discussed how the head and neck domains of myosins function as a motor that converts chemical energy into mechanical force. In this section, we discuss how the whole myosin motor molecules work and are regulated. Since the functions of many of the families of myosins found in metazoans are not yet known, we look at three examples for which we have a good idea of specific myosin function. Our first example is skeletal muscle. In muscle, many myosin II heads, each with a low duty ratio, are bundled into bipolar filaments that work together to bring about muscle contraction. Contractile machinery also functions in the contraction of smooth muscle, in stress fibers, and in the contractile ring during cytokinesis. In our second example, we will look at how contraction operates in nonskeletal muscle. In the third example, we turn to the myosin V class, whose high duty ratio allows cargo to be transported over relatively long distances.

Myosin Thick Filaments and Actin Thin Filaments in Skeletal Muscle Slide Past Each Other During Contraction

Muscle cells have evolved to carry out one highly specialized function: contraction. Muscle contractions must occur quickly and repetitively, and they must occur over long distances and with

enough force to move large loads. A typical skeletal muscle cell is cylindrical, large (1–40 mm in length and 10–50 μm in width), and multinucleated (containing as many as 100 nuclei) (Figure 17-29a). Within each muscle cell are many **myofibrils** consisting of a repeating array of a specialized structure called a **sarcomere** (Figure 17-29b). A sarcomere, which is about 2 μm long in resting muscle, shortens by about 70 percent of its length during contraction. Electron microscopy and biochemical analysis have shown that each sarcomere contains two major types of filaments: **thick filaments**, composed of myosin II, and **thin filaments**, containing actin and associated proteins (Figure 17-29c).

FIGURE 17-29 Structure of the skeletal muscle sarcomere. (a) Skeletal muscles consist of muscle fibers made of bundles of multinucleated cells. Each cell contains a bundle of myofibrils, which consist of thousands of repeating contractile structures called *sarcomeres*. (b) Electron micrograph of mouse skeletal muscle in longitudinal section, showing one sarcomere. On either side of the Z disks are the lightly stained I bands, composed entirely of actin thin filaments. These thin filaments extend from both sides of the Z disk to interdigitate with the dark-stained myosin thick filaments in the A band. (c) Diagram of the arrangement of myosin and actin filaments in a sarcomere.

The thick filaments are made of many myosin II bipolar filaments, in which the heads on each half of the filament are in opposite orientations (see Figure 17-22a). The thin actin filaments are assembled with their (+) ends embedded in a densely staining structure known as the *Z disk*, so that the two sets of actin filaments

in a sarcomere have opposite orientations (Figure 17-30). To understand how a muscle contracts, consider the interactions between one myosin head (among the hundreds in a thick filament) and one thin (actin) filament, as diagrammed in Figure 17-26. During these cyclical interactions, also called the *cross-bridge cycle*, the hydrolysis of ATP is coupled to the movement of a myosin head toward the Z disk, which corresponds to the (+) end of the actin thin filament. Because the thick filament is bipolar, the action of the myosin heads at opposite ends of the thick filament draws the thin filaments toward the center of the thick filament and therefore toward the center of the sarcomere (see Figure 17-30). This movement shortens the sarcomere until the ends of the thick filaments abut the Z disk. Contraction of an intact muscle results from the activity of hundreds of myosin heads on a single thick filament, amplified by the hundreds of thick and thin filaments in a sarcomere and thousands of sarcomeres in a muscle fiber. We can now see why myosin II is both nonprocessive and needs to have a low duty ratio: each head pulls a short distance on the actin filament and then lets go to allow other heads to pull, and so many heads working together allow the smooth contraction of the sarcomere. The first experimental basis for the sliding-filament model of muscle contraction is highlighted in Classic Experiment 17-1.

FIGURE 17-30 The sliding-filament model of contraction in skeletal muscle. The arrangement of thick myosin and thin actin filaments in the relaxed state is shown in the top diagram. In the presence of ATP and Ca^{2+}, the myosin heads extending from the thick filaments walk toward the $(+)$ ends of the thin filaments. Because the thin filaments are anchored at the Z disks (purple), movement of myosin pulls the actin filaments toward the center of the sarcomere, shortening its length in the contracted state, as shown in the bottom diagram.

The human heart is an amazing contractile organ — it contracts without interruption about 3 million times a year, or a fifth of a billion times in a lifetime. The muscle cells of the heart contain contractile machinery very similar to that of skeletal muscle, except

that they are mono- and bi-nucleated cells. In each cell, the end sarcomeres insert into structures at the plasma membrane called *intercalated disks*, which link the cells into a contractile chain. Heart muscle cells are generated only early in life, so they cannot be replaced in response to damage, such as occurs during a heart attack. Many different mutations in proteins of the heart contractile machinery give rise to *hypertrophic cardiomyopathies* — thickening of the heart wall muscle, which compromises its function. For example, many mutations have been documented in the cardiac myosin heavy-chain gene that compromise the protein's contractile function even in heterozygous individuals. In such individuals, the heart tries to compensate by hypertrophy (enlargement), which often results in fatal heart arrhythmia (irregular beating). In addition to myosin heavy-chain defects, defects that result in cardiomyopathies have been traced to mutations in other components of the contractile machinery, including actin, myosin light chains, tropomyosin and troponin, and structural components such as titin (discussed below). ■

Skeletal Muscle Is Structured by Stabilizing and Scaffolding Proteins

The structure of the sarcomere is maintained by a number of accessory proteins (Figure 17-31). The actin filaments are stabilized on their (+) ends by CapZ and on their (−) ends by tropomodulin

(see Section 17.2). A giant protein known as *nebulin* extends along the thin filament all the way from the Z disk to tropomodulin, to which it binds. Nebulin consists of repeating domains that bind to actin subunits in the filament, and it is believed that the number of actin-binding repeats, and therefore the length of nebulin, determines the length of the thin filaments. Another giant protein, called *titin*, has its head associated with the Z disk and extends to the M band in the middle of the thick filament, where another titin molecule extends to the subsequent Z disk. Titin is believed to be an elastic molecule that holds the thick filaments in the middle of the sarcomere and also prevents overstretching to ensure that the thick filaments remain interdigitated between the thin filaments.

FIGURE 17-31 Accessory proteins found in skeletal muscle. To stabilize the actin filaments, CapZ caps the (+) end of the thin filaments at the Z disk, whereas tropomodulin caps the (−) end. The giant protein titin extends from the M band through the thick filaments and attaches to the Z disk. Nebulin binds actin subunits and determines the length of the thin filament.

Contraction of Skeletal Muscle Is Regulated by Ca^{2+} and Actin-Binding Proteins

Like many cellular processes, skeletal muscle contraction is initiated by an increase in the cytosolic Ca^{2+} concentration. As described in Chapter 11, the Ca^{2+} concentration of the cytosol is normally kept below 0.1 μM. In skeletal muscle cells, a low cytosolic Ca^{2+} level is maintained primarily by a unique Ca^{2+} ATPase that continually pumps Ca^{2+} ions from the cytosol containing the myofibrils into the **sarcoplasmic reticulum (SR)**, a specialized endoplasmic reticulum of muscle cells (Figure 17-32). This activity establishes a reservoir of Ca^{2+} in the SR.

FIGURE 17-32 The sarcoplasmic reticulum regulates the level of free Ca^{2+} in myofibrils. (a) When a nerve impulse stimulates a muscle cell, the action potential is transmitted down a transverse tubule (yellow), which is continuous with the plasma membrane (sarcolemma), leading to release of Ca^{2+} from the adjacent sarcoplasmic reticulum (blue) into the myofibrils. (b) Thin-section electron micrograph of skeletal muscle, showing the intimate relationship of the sarcoplasmic reticulum to the muscle fibers.

The arrival of a nerve impulse (or *action potential*; see Chapter 23) at a neuromuscular junction triggers an action potential in the muscle-cell plasma membrane (also known as the *sarcolemma*). The action potential travels down invaginations of the plasma membrane known as *transverse tubules*, which pass into the cell and lie around each myofibril. The arrival of the action potential in the transverse tubules stimulates the opening of voltage-gated Ca^{2+} channels in the SR membrane, and the ensuing release of Ca^{2+} from the SR raises the cytosolic Ca^{2+} concentration in the myofibrils. This elevated Ca^{2+} concentration induces changes in two accessory proteins, tropomyosin and troponin, which are bound to the actin thin filaments and normally block myosin binding. Changes in the positions of these proteins on the actin thin filaments in turn permit

the myosin-actin interactions and hence contraction. This type of regulation is very rapid and is known as *thin-filament regulation*.

Tropomyosin (TM) is a ropelike molecule, about 40 nm in length, that binds to seven actin subunits in an actin filament. TM molecules are strung together head to tail, forming a continuous chain along each side of the actin thin filament (Figure 17-33a, b). Associated with each TM molecule is *troponin* (TN), a complex of three subunits, TN-T, TN-I, and TN-C. TN-C is the calcium-binding subunit of troponin; it controls the position of TM on the surface of an actin filament through the TN-I and TN-T subunits.

FIGURE 17-33 Ca^{2+}-dependent thin-filament regulation of skeletal muscle contraction. (a) Model and the corresponding structure of the tropomyosin-troponin regulatory complex on a thin filament. Troponin is a protein complex that is bound to the long α-helical tropomyosin molecule. (b) Three-dimensional electron-microscope reconstructions of the tropomyosin helix (yellow) on a muscle thin filament. Tropomyosin in the relaxed state (*top*) shifts to a new position (arrows) in the state inducing contraction (*bottom*) when the Ca^{2+} concentration in the sarcoplasm increases. This movement exposes myosin-binding sites (red) on actin. (Troponin is not shown in this representation, but it remains bound to tropomyosin in both states.) (c) Summary of the regulation of skeletal muscle contraction by Ca^{2+} binding to troponin.

[Part (a) Data from S. Wu et al., 2012, *PLOS One* **7**:39422, PDB ID 2w4u. Part (b) P. Vibert, R. Craig, and W. Lehman, 1993, *J. Cell Biol.* **123**(2):313–321; https://doi.org/10.1083/jcb.123.2.313.]

Under the control of Ca^{2+} and TN, TM can occupy either of two positions on a thin filament. In the absence of Ca^{2+}, TM blocks myosin's interaction with F-actin, and the muscle is relaxed. Binding of Ca^{2+} ions to TN-C triggers movement of TM to a new position on the filament, thereby exposing the myosin-binding sites on actin (Figure 17-33b). Thus at Ca^{2+} concentrations greater than 1 μM the inhibition exerted by the TM-TN complex is relieved, and contraction occurs. The Ca^{2+}-dependent cycling between relaxation and contraction states in skeletal muscle is summarized in Figure 17-33c.

Heart muscle, like skeletal muscle, is subject to thin-filament regulation, using cardiac-specific tropomyosin and troponin. During a heart attack (myocardial infarction), heart cells are deprived of

sufficient oxygen (cardiac ischemia) and may subsequently die. The plasma membrane of the dead cells ruptures and releases cellular components into the bloodstream. Blood tests that specifically measure the level of cardiac-specific troponins are used by physicians to determine the severity of a heart attack. ■

Actin and Myosin II Form Contractile Bundles in Nonmuscle Cells

In skeletal muscle, as we have seen, actin thin filaments and myosin II thick filaments assemble into highly organized contractile structures. Nonmuscle cells contain several types of **contractile bundles** composed of actin and myosin II filaments, which are similar to skeletal muscle fibers but much less organized. Moreover, these contractile bundles lack the troponin regulatory system and are instead regulated by myosin phosphorylation, as we discuss below. Let's look at a few examples.

In epithelial cells, contractile bundles are most commonly found as an adherens belt, also known as the *circumferential belt*, that encircles the inner surface of the cell at the level of the adherens junction (see Figure 17-4a). These bundles are important in maintaining the integrity of the epithelium (discussed in Chapter 20). A second type of contractile bundle are stress fibers, which are seen along the lower surfaces of cells cultured on artificial (glass or

plastic) surfaces or on extracellular matrices (see Figure 17-4a, b) and are important in cell adhesion. The ends of stress fibers terminate at integrin-containing focal adhesions, special structures that attach a cell to the underlying substratum (see Figure 17-39b, c and Chapter 20). Circumferential belts and stress fibers contain several proteins found in the contractile apparatus of smooth muscle and exhibit some organizational features resembling those of muscle sarcomeres. A third type of contractile bundle is the contractile ring, a transient structure in animal cells that assembles at the equator of a dividing cell, encircling the cell midway between the poles of the mitotic spindle (Figure 17-34a). As the ring contracts, pulling the plasma membrane in, the cytoplasm is divided and eventually pinched into two parts in a process known as *cytokinesis*, giving rise to two daughter cells. In a dividing cell expressing GFP-myosin-II, myosin II is localized to the contractile ring (Figure 17-34b). As evidence for the role of myosin II in forming the cleavage furrow, when the gene for the heavy chain of myosin II has been deleted, cells are unable to undergo cytokinesis. Instead, these cells form a multinucleated syncytium because cytokinesis, but not nuclear division, is inhibited.

EXPERIMENTAL FIGURE 17-34 Localization of myosin II during cytokinesis. (a) Diagram of a cell going through cytokinesis, showing the mitotic spindle (microtubules green, chromosomes blue) and the contractile ring with actin filaments (red). (b) Fluorescence micrograph of a *Dictyostelium* amoeba expressing GFP-myosin-II reveals myosin-II enrichment in the cleavage furrow cortex, as the cell pinches into two during cytokinesis.

Myosin-Dependent Mechanisms Regulate Contraction in Smooth Muscle and Nonmuscle Cells

Like skeletal muscle, smooth muscle is composed of contractile cells. Smooth muscle is found in the walls of hollow organs and the walls of passageways. For example, smooth muscle surrounds blood vessels to regulate blood pressure, surrounds the intestine to move food through the gut, and restricts airway passages in the lung. The contractile apparatus of smooth muscle and its regulation are a valuable model for studying these processes because contraction in

smooth muscle is regulated in a manner similar to that in nonmuscle cells. As we have just seen, in skeletal muscle the activity of the myosin II is not directly regulated, but its accessibility to F-actin is regulated by the tropomyosin-troponin complex bound to the actin thin filament that switches between the contraction-inducing state in the presence of Ca^{2+} and the relaxed state in its absence. In contrast, smooth muscle contraction is regulated by the cycling of myosin II between on and off states. Myosin II cycling, and thus contraction of smooth muscle and nonmuscle cells, is regulated in response to many extracellular signaling molecules.

Contraction of vertebrate smooth muscle is regulated primarily by a pathway in which the *myosin regulatory light chain (LC)* associated with the myosin II neck domain (see Figure 17-22b) undergoes phosphorylation and dephosphorylation. When the regulatory LC is not phosphorylated, smooth muscle myosin II folds into a self-inhibited state where its ATPase cycle is inactive. When the regulatory LC is phosphorylated by the enzyme **myosin light-chain kinase (MLC kinase)**, myosin II opens up by unfolding, assembles into filaments, and becomes able to induce contraction (Figure 17-35). The activity of MLC kinase is regulated by the level of free Ca^{2+} in the cytoplasm. The Ca^{2+}-dependent regulation of MLC kinase activity is mediated by the Ca^{2+}-binding protein calmodulin (see Figure 3-34). When an extracellular signal leads to a rise in intracellular free Ca^{2+} concentration, Ca^{2+} binds to calmodulin inducing a conformational change in the protein. The

Ca^{2+}/calmodulin complex then binds to MLC kinase and activates it. This enables MLC kinase to phosphorylate the myosin regulatory LC. When the cytosolic Ca^{2+} concentration returns to its resting level, MLC kinase becomes inactive, and myosin light-chain phosphatase removes the phosphates from myosin, which returns the system to its relaxed state. This mode of regulation relies on the action of a protein kinase and on the diffusion of Ca^{2+} over greater distances than in sarcomeres, so contraction is slower in smooth muscle than in skeletal muscle. Because this regulation involves myosin, it is known as *thick-filament regulation*.

FIGURE 17-35 Myosin light-chain phosphorylation regulates smooth muscle contraction. In vertebrate smooth muscle, phosphorylation of the myosin regulatory light chain (LC) activates contraction. At Ca^{2+} concentrations of less than 10^{-6} M, the regulatory light chain is not phosphorylated, and the myosin adopts a folded conformation. When the Ca^{2+} level rises, Ca^{2+} binds calmodulin (CaM), which undergoes a conformational change (CaM*). The CaM*-Ca^{2+} complex binds and activates myosin light-chain kinase (MLC kinase), which then phosphorylates the myosin LC. This phosphorylation event opens myosin II, which assembles into side-polar filaments that participate in contraction. Note that the organization of side-polar filaments is distinct from

that of the bipolar filaments seen in skeletal muscle. When Ca^{2+} levels drop, the myosin LC is dephosphorylated by myosin light-chain (MLC) phosphatase, causing muscle relaxation.

Unlike skeletal muscle, which is stimulated to contract solely by nerve impulses, smooth muscle cells and nonmuscle cells are regulated by many types of external signals. For example, norepinephrine, angiotensin, endothelin, histamine, and other signaling molecules modulate or induce the contraction of smooth muscle or elicit changes in the shape and adhesion of nonmuscle cells by triggering various signal transduction pathways. Some of these pathways lead to an increase in the cytosolic Ca^{2+} concentration, which can stimulate myosin activity by activating MLC kinase (see Figure 17-35). As we will see in Section 17.7, other signaling pathways activate *Rho kinase*, which also activates myosin activity by phosphorylating the regulatory light chain, but in a Ca^{2+}-independent manner.

Myosin V Carries Vesicles Along Actin Filaments

The myosin V family of proteins transport cargo along actin filaments and are the most processive myosin motors known. In the next chapter we discuss how they work in conjunction with microtubule motors to transport organelles. Here we look at how these motors carry endocytic and secretory vesicles around the cell.

Much is known about myosin V motors in experimentally accessible systems such as the budding yeast *Saccharomyces cerevisiae*. This well-studied organism grows by budding, which requires its secretory machinery to target newly synthesized materials to the growing bud (Figure 17-36a). Myosin V transports secretory vesicles along actin filaments at 3 μm/s to grow the bud (Figure 17-36b). Myosin V proteins are also important at a later stage of the yeast cell cycle, when the organelles have to be distributed between the mother and daughter cells. Myosin V molecules in yeast transport some of the mother cell's peroxisomes, mitochondria, vacuoles, endoplasmic reticulum, the *trans*-Golgi network, and even the ends of microtubules and some specific messenger RNAs into the bud (Figure 17-36c). These organelles each have a distinct receptor that the tail of myosin V binds to. The motor makes many delivery cycles, so it has to have a way to pick up, transport, and deliver its organelle cargo. Recent work has shown that myosin V can exist in two states: an inactive folded state in which the tail domain binds and inhibits the activity of the motor head domain, and an active state in which binding to cargo unfolds the tail, thus releasing the head from the tail, which allows the myosin motor to operate (Figure 17-36d, e). How the motor releases its cargo upon delivery is poorly understood — although in one case, it is known that the receptor on the organelle that binds myosin becomes degraded upon delivery of the organelle to its destination. Whereas budding yeast use myosin V and polarized actin filaments to transport many organelles, animal cells employ microtubules and their motors to transport many of the

same organelles over the longer distances inside an animal cell. We discuss those transport mechanisms in the next chapter.

FIGURE 17-36 Cargo movement by myosin V. (a) The yeast *Saccharomyces cerevisiae* (used in making bread, beer, and wine) grows by budding. (b) Secretory vesicles are transported by myosin V along actin cables, nucleated by formins, into the bud, which grows to swell to

about the size of the mother cell. (c) Before cell division can occur, all the organelles must be segregated between the mother and the bud, including the vacuole (the yeast equivalent of a lysosome), peroxisomes, mitochondria, endoplasmic reticulum (ER), *trans*-Golgi network (TGN), and even selected mRNAs into the bud, which are all mediated by myosin V. Myosin V also binds the ends of cytoplasmic microtubules (green) to orient the nucleus in preparation for mitosis. See D. Pruyne et al., 2004, *Ann. Rev. Cell Dev. Biol.* **20**:559. (d) Myosin V is regulated by binding cargo. In the inactive folded state, the tails of myosin V bind and inactivate the motor head domains. Upon cargo binding, the head-to-tail interaction is alleviated, and the motor is now active to transport cargo. (e) Electron micrograph of inactive myosin V. Myosin V molecules were negatively stained and viewed in a transmission electron microscope. The image shown is the composite average from several individual images.

Perhaps the most dramatic example of movement by myosin V is seen in giant green algae, such as *Nitella* and *Chara*. These algae can be found in ponds during the summer and their movement easily observed using a simple microscope. In their large cells, which can be as much as 2 cm in length, cytosol flows rapidly, at a rate approaching 4.5 mm per minute, in an endless loop around the inner circumference of the cell (Figure 17-37). This *cytoplasmic streaming* is a principal mechanism for distributing cellular metabolites and is also seen in other large cells such as plant cells and amoebae. The algal cells have bundles of actin filaments aligned along the length of the cell, lying just above the stationary chloroplasts located adjacent to the membrane. The bulk cytosol is propelled by myosin V (also known as *myosin XI* in plants) attached

to parts of the ER adjacent to the actin filaments. The flow rate of the cytosol in *Nitella* is about 15 times faster than movement produced by any other myosins. ■

FIGURE 17-37 Cytoplasmic streaming in cylindrical giant algae. (a) Cells of *Nitella*, a freshwater alga commonly found in ponds in the summer. The cytoplasmic movement, described below, can be readily observed with a simple microscope, so go find some *Nitella* (or related algae) and watch this amazing phenomenon! (b) The center of a *Nitella* cell is filled with a single large water-filled vacuole, which is surrounded by a layer of moving cytoplasm (blue arrows). A nonmoving layer of cortical cytoplasm filled with chloroplasts lies just under the plasma membrane (enlarged in bottom figure). On the inner side of this layer are bundles of stationary actin filaments (red), all oriented with the same polarity. A motor protein (blue), a plant myosin V, carries parts of the endoplasmic reticulum (ER) along the actin filaments. The movement of the ER network propels the entire viscous cytoplasm,

including organelles that are enmeshed in the ER network. (c) Electron micrograph of the cortical cytoplasm showing a large vesicle connected to an underlying bundle of actin filaments.

KEY CONCEPTS OF SECTION 17.6

Myosin-Powered Movements

- In skeletal muscle, contractile myofibrils are composed of thousands of repeating units called *sarcomeres*. Each sarcomere consists of two interdigitating filament types: myosin thick filaments and actin thin filaments (see Figure 17-29).
- Skeletal muscle contraction involves the ATP-dependent sliding of myosin thick filaments along actin thin filaments to shorten the sarcomere and hence the myofibril (see Figure 17-30).
- The ends of the actin thin filaments in skeletal muscle are stabilized by CapZ at the $(+)$ end and by tropomodulin at the $(-)$ end. Two large proteins, nebulin associated with the thin filaments and titin with the thick filaments, also contribute to skeletal muscle organization.
- Skeletal muscle contraction is subject to thin-filament regulation. At low levels of free Ca^{2+}, tropomyosin blocks the interaction of myosin and F-actin, and the muscle is relaxed. At elevated levels of free Ca^{2+}, the troponin complex associated with tropomyosin binds Ca^{2+} and moves the tropomyosin to uncover the myosin-binding sites on actin, allowing contraction (see Figure 17-33).
- Smooth muscle and nonmuscle cells have contractile bundles of actin and myosin filaments with an organization similar to that in skeletal muscle but less well ordered.
- Contractile bundles are subject to thick-filament regulation. A myosin light chain is phosphorylated by myosin light-chain kinase, which activates myosin and hence induces contraction. The MLC kinase is activated by binding to Ca^{2+}-calmodulin when the free intracellular Ca^{2+} concentration rises (see Figure 17-35).
- Inactive myosin V is activated by binding cargo, which it transports processively along actin filaments.

17.7 Cell Migration: Mechanism, Signaling, and Chemotaxis

So far in this chapter, we have examined some of the mechanisms cells use to create movement using actin, myosin, and other actin-associated proteins. Some of these mechanisms generate the forces used by cells to migrate. **Cell migration** results from the coordination of actin-based motions generated in different parts of a cell, which are integrated with an endocytic cycle.

The study of cell migration is important to many fields of biology and medicine. For example, an essential feature of animal development is the migration of specific cells along predetermined paths. Epithelial cells in an adult animal migrate to heal a wound, and white blood cells migrate to sites of infection. Less obvious are the continuous slow migration of intestinal epithelial cells along the villi in the intestine and of endothelial cells that line the blood vessels. The inappropriate migration of cancer cells after breaking away from their normal tissue results in metastasis.

Cell migration is initiated by the formation of a large, broad membrane protrusion at the leading edge of a cell. Video microscopy reveals that a major feature of this movement is the polymerization of actin at the membrane. Actin filaments at the leading edge are rapidly cross-linked into bundles and networks in a protruding region, called a *lamellipodium* in vertebrate cells. In

some cases, slender, fingerlike membrane projections, called *filopodia*, also extend from the leading edge. These structures form stable contacts with the underlying surface (e.g., the extracellular matrix) that the cell moves across. In this section, we take a closer look at how cells coordinate various microfilament-based processes with endocytosis to move across a surface. We also consider the role signaling pathways play in coordinating and integrating the actions of the cytoskeleton, a major focus of current research.

Cell Migration Coordinates Force Generation with Cell Adhesion and Membrane Recycling

If you watch a moving fibroblast (connective tissue cell), it displays a characteristic sequence of events as it migrates over a surface: initial extension of a membrane protrusion, attachment to the substratum, forward flow of cytosol, and retraction of the rear of the cell (Figure 17-38). These events occur in an ordered pattern in a slowly moving cell such as a fibroblast, but in rapidly moving cells, such as macrophages, all four steps occur simultaneously in a coordinated manner. In this section, we first consider the role the actin cytoskeleton plays in assembly at the leading edge as well as attachment to (and detachment from) the substratum (Figure 17-39a, b). Second, we discuss the role of the endocytic cycle in cell migration.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 17-38 Steps in cell locomotion. Movement begins with the extension of one or more lamellipodia from the leading edge of the cell (step 1); some lamellipodia adhere to the substratum by focal adhesions (step 2). Then the bulk of the cytoplasm in the cell body flows forward due to contraction at the rear of the cell (step 3). The trailing edge of the cell remains attached to the substratum until the tail eventually detaches and retracts into the cell body. During this cytoskeleton-based cycle, the endocytic cycle internalizes

membrane and integrins at the rear of the cell and transports them to the front of the cell (arrows) for reuse in making new adhesions (step **4**).

FIGURE 17-39 Actin-based structures involved in cell locomotion. (a) Localization of actin in a fibroblast expressing GFP-actin. (b) Diagram of the classes of microfilaments involved in cell migration. The network of actin filaments in the leading edge advances the cell forward. Contractile fibers in the cell cortex squeeze the cell body forward, and stress fibers terminating in focal adhesions also pull the bulk of the cell body up as the rear adhesions are released. (c) The structure of focal adhesions involves the attachment of the ends of stress fibers through integrins to the underlying extracellular matrix. Focal adhesions also contain many signaling molecules important for cell locomotion. (d) The dynamic actin network in the leading edge is nucleated by the $\mathrm{Arp2/3}$ complex and employs the same set of factors that control assembly and disassembly of actin filaments in the *Listeria* tail (see Figure 17-17).

Step 1: Membrane Extension

The network of actin filaments at the leading edge is a type of cellular engine that pushes the membrane forward in a manner very similar to the propulsion of *Listeria* by actin polymerization (Figure 17-39d; for *Listeria*, see Figure 17-17c). At the membrane of the leading edge, actin is nucleated by the activated Arp2/3 complex (see Figure 17-15), and filaments are elongated by assembly onto (+) ends adjacent to the plasma membrane. Because the actin network is fixed with respect to the substratum, the front membrane is pushed out as the filaments elongate. Actin turnover, and thus treadmilling, is mediated, as it is in the comet tails of *Listeria*, by the action of profilin and cofilin (Figure 17-39d).

Step 2: Cell-Substratum Adhesions

When the membrane has been extended and the actin network has been assembled, the plasma membrane becomes firmly attached to the substratum. Time-lapse microscopy shows that actin bundles in the leading edge become anchored to structures known as *focal adhesions* (Figure 17-39c). The membrane proteins within a focal adhesion that connect actin bundles to the extracellular matrix are called *integrins*. Integrins have an external domain that binds to specific components of the extracellular matrix, such as fibronectin and collagen, and a cytoplasmic domain that links them to the actin cytoskeleton (see Figure 17-39c and Chapter 20). The attachment of

cell to substrate serves two purposes: it prevents the lamellipodium from retracting, and it allows the cell to move forward. Given the importance of focal adhesions and their regulation during cell locomotion, it is not surprising that they are very rich in molecules involved in signal transduction pathways. Focal adhesions are discussed in Chapter 20, where we discuss in detail the interactions that occur between a cell and the extracellular matrix.

Step 3: Cell-Body Translocation

After the forward adhesions at the leading edge have been made, the bulk contents of the cell body are translocated forward (see Figure 17-38, step **3**). The nucleus and the other organelles embedded in the cytoskeleton are moved forward by myosin II–dependent cortical contraction in the rear part of the cell, like toothpaste when the lower half of the tube is squeezed. Consistent with this model, myosin II is localized to the rear cell cortex. As the cell migrates forward, the adhesions effectively move toward the rear of the cell.

Step 4a: Breaking Cell Attachments

Finally, in the last step of movement, the focal adhesions at the rear of the cell are broken (de-adhesion), the integrins are recycled, and the freed tail of the cell is brought forward. In the light microscope, the tail is often seen to snap loose from its connections — perhaps by the contraction of stress fibers in the tail or by elastic tension —

and it sometimes leaves a little bit of its membrane behind, still firmly attached to the substratum.

Cells cannot move as just described if they are either too strongly attached or too weakly attached to a surface. The ability of a cell to move corresponds to a balance between the mechanical forces generated by the cytoskeleton and the resisting forces generated by cell adhesions. This relationship can be demonstrated by measuring the rate of movement in cells that express varying levels of integrins. Such measurements show that the fastest migration occurs at an intermediate level of adhesion, with the rate of movement falling off at high and low levels of adhesion. Cell locomotion thus results from traction forces exerted by the cell on the underlying substratum.

Step 4b: Recycling Membrane and Integrins by Endocytosis

The dynamic changes in the actin cytoskeleton alone are not sufficient to drive cell migration. It is also dependent on endocytic recycling of plasma membrane. The membrane needed during lamellipodium extension is provided by internal endosomes as the membrane recycles back to the cell surface. Adhesion molecules in focal adhesions at the rear of the cell are internalized as those adhesions are disassembled and are then transported by an endocytic cycle to the front of the cell to make new substratum attachments at the leading edge (see Figure 17-38, step **4**). This

cycling of adhesion molecules in a migrating cell resembles the way a tank uses its treads to move forward. The movement of membrane internally through the cell also generates a rearward membrane flow across the surface of the cell. Indeed, this type of flow may contribute to the mechanics of cell locomotion, as it has been found that white blood cells can move in a liquid (i.e., "swim") in the absence of attachment to a substratum, presumably as surface structures operating like paddles move backward across the cell surface.

The Small GTP-Binding Proteins Cdc42, Rac, and Rho Control Actin Organization

A striking feature of a moving cell is its polarity: it has a front and a back. In addition, when a cell makes a turn, a new leading edge forms in the new direction of movement. To sustain movement in a particular direction, a cell requires signals to coordinate events at the front of the cell with events at the back and, indeed, signals to tell the cell where its front is. Our understanding of how this coordination occurs has emerged from studies of growth factors.

Growth factors, such as epidermal growth factor (EGF) and platelet-derived growth factor (PDGF), bind to specific cell-surface receptors (see Chapter 16) and consequently stimulate cells to move or to

divide. For example, in a wound, activated blood platelets secrete PDGF to attract fibroblasts and epithelial cells to enter the wound and repair it. It is possible to watch part of this process in vitro. If you grow cells in a culture dish and, after starving them of growth factors, you add some fresh growth factor, within a minute or two the cells respond by forming membrane ruffles. The growth factor activates cellular components that control recycling of membrane from endosomes coupled with actin assembly. In this regard, membrane ruffles are very similar to the lamellipodia of migrating cells.

Growth factors bind to specific receptors on the cell surface and induce a signal transduction pathway on the inner surface of the plasma membrane (see Chapter 15). The signal transduction pathway activates **Rac**, a member of the small GTPase superfamily of Ras-related proteins. Rac is one member of a GTPase superfamily that regulates microfilament organization; two others are **Cdc42** and **Rho**. (Due to the history of their discovery, the protein family of which Cdc42, Rac, and Rho are members has been collectively named "Rho proteins.") To understand how these proteins work, we first have to recall how small GTP-binding proteins function (see Chapter 15).

Like all small GTPases of the Ras superfamily, Cdc42, Rac, and Rho act as molecular switches: inactive in the GDP-bound state and active in the GTP-bound state (Figure 17-40). In their GDP-bound state, they exist free in the cytoplasm in an inactive form bound to a

protein known as *guanine nucleotide dissociation inhibitor (GDI)*. Growth factors can bind and activate their receptors to turn on specific membrane-bound regulatory proteins, called *guanine nucleotide exchange factors (GEFs)*, which activate Rho proteins at the membrane by releasing them from GDI and catalyzing the exchange of GDP for GTP. The GTP-bound active Rho protein associates with the plasma membrane, where it binds *effector proteins* to transmit the biological response. The small GTPase remains active until the GTP is hydrolyzed to GDP, a process that is stimulated by specific GTPase-activating proteins (GAPs).

FIGURE 17-40 Regulation of the Rho family of small GTPases. The small GTPases of the Rho family are molecular switches regulated by accessory proteins. Rho proteins exist in the Rho-GDP bound form complexed with a protein known as *GDI (guanine nucleotide dissociation inhibitor)*, which keeps them in an inactive state in the cytosol. Membrane-bound signaling pathways bring Rho proteins to the membrane and, through the action of a GEF (guanine nucleotide exchange factor), exchange the GDP for GTP, thus activating them. Membrane-bound activated Rho-GTP can then bind effector proteins that

cause changes in the actin cytoskeleton. The Rho protein remains in the active Rho-GTP state until acted on by a GAP (GTPase-activating protein), which allows it to interact with the GDI and be returned to the cytoplasm. See S. Etienne-Manneville and A. Hall, 2002, *Nature* **420**:629.

To unravel the functions of the Rho proteins in cell migration, cells were modified to express mutant proteins that were locked either in the active Rho-GTP state or in the inactive Rho-GDP state. In general, a small GTPase that is locked in the active state is called a *dominant-active* protein. This always active GTPase will constitutively bind effector proteins (Figure 17-40), and one can then assess the biological outcomes. Alternatively, a *dominant-negative protein* can be introduced into a cell, such as a protein that binds to and inhibits the GEF protein. Introduction of a dominant-negative protein interferes with the signal transduction pathway, enabling one to assess what processes are blocked.

When experiments like these were performed in fibroblasts, Cdc42, Rac, and Rho were implicated in the regulation of microfilament organization because introduction of dominant-active mutant proteins had dramatic effects on the actin cytoskeleton, even in the absence of growth factors. Dominant-active Cdc42 resulted in the appearance of filopodia, dominant-active Rac resulted in the appearance of membrane ruffles, and dominant-active Rho resulted in the formation of stress fibers, which were seen to contract (Figure 17-41). How can one tell if dominant-active Rac and growth factor stimulation, both of which stimulate membrane ruffle formation,

use the same signal transduction pathway? If growth factor stimulation leads to Rac activation, then introduction of a dominant-negative Rac protein into a cell should block the ability of a growth factor to induce membrane ruffling. This is precisely what was found. Using this and many other biochemical strategies, scientists have identified the signaling pathways involving Cdc42, Rac, and Rho (Figure 17-42).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 17-41 Dominant-active Rac, Rho, and Cdc42 induce different actin-containing structures. To look at the effects of constitutively active Rac, Rho, and Cdc42, growth-factor-starved fibroblasts were microinjected with plasmids to express dominant-active versions of the three proteins. The cells were then treated with fluorescent phalloidin, which stains filamentous actin. Dominant-active Rac induces the formation of peripheral membrane ruffles, whereas dominant-active Rho induces abundant contractile stress fibers, and dominant-active Cdc42 induces filopodia.

FIGURE 17-42 Summary of signal-induced changes in the actin cytoskeleton. Specific signals, such as growth factors and lysophosphatidic acid (LPA), are detected by cell-surface receptors. Detection leads to the activation of the small GTP-binding proteins, which then interact with effectors to bring about cytoskeletal changes as indicated.

Some of the pathways that these proteins regulate contain proteins we are familiar with. Activation of Cdc42 stimulates actin assembly by Arp2/3 through activation of WASp, a nucleation promoting factor (NPF) (see Figure 17-16), resulting in the formation of filopodia. Activation of Rac also induces Arp2/3, mediated by the WAVE complex, leading to the assembly of branched actin filaments in the leading edge. Activation of Rho has at least two effects. First, it can activate a formin for unbranched actin filament assembly. Second, through activation of Rho kinase, it can phosphorylate the myosin light chain to activate nonmuscle myosin II and can also inhibit light-chain dephosphorylation by phosphorylating myosin light-chain phosphatase to inhibit its activity. Both actions of Rho kinase lead to a higher level of myosin light-chain phosphorylation and therefore higher myosin activity and contraction. Cdc42, Rac, and Rho are also linked by activation and inhibition pathways, as shown in Figure 17-42.

Cell Migration Involves the Coordinate Regulation of Cdc42, Rac, and Rho

How does each of these small GTP-binding proteins contribute to cell migration? To answer this question, researchers developed the wounded-cell monolayer assay (Figure 17-43a). Cells in culture are grown in a petri dish with growth factors until they are confluent and form a tight monolayer, at which point they stop dividing. The cell monolayer is then scratched with a needle to remove a swath of cells, generating a wound containing a free edge of cells. The cells on the edge sense the loss of their neighbors and, in response to components of the extracellular matrix now exposed on the dish surface, move to fill up the empty wound area (Figure 17-43b). To do this, they orient themselves toward the empty area, first extending a lamellipodium and then moving in that direction. In this way, one can study the induction of directed cell migration in vitro.

EXPERIMENTAL FIGURE 17-43 The wounded-cell monolayer assay can be used to dissect signaling pathways in directed cell movement. (a) A confluent layer of cells is scratched to remove a swath about three cells wide to generate a free cell border. The remaining cells detect the free space and newly exposed extracellular matrix and, over a period of hours, fill in the area. (b) Localization of actin in a wounded monolayer 5 minutes and 3 hours after scratching; after 3 hours, cells have migrated into the wounded area. (c) Effect of introducing dominant-negative Cdc42, Rac, and Rho into cells at the wound edge; all affect wound closure.

[Part (b, c) C. D. Nobes and A. Hall, 1999, *J. Cell Biol.* **144**(6):1235–1244; https://doi.org/10.1083/jcb.144.6.1235.]

Using this wounded-cell monolayer assay, researchers have introduced dominant-negative Rac into cells on the wound edge to see how it affects the ability of the cells to migrate and fill the wound. Since Rac is needed for activation of the Arp2/3 complex to form the lamellipodium, it is not surprising that cells containing dominant-negative Rac fail to form this structure and do not migrate, and so the wound does not close (Figure 17-43c). A very interesting result is obtained when dominant-negative Cdc42 is introduced into the cells at the wound edge: they can form a lamellipodium, but they do not orient in the correct direction — in fact, they try to migrate in random directions. This observation suggests that Cdc42 is critical for regulating the overall polarity of the cell. Studies from yeast (in which Cdc42 was first described), wounded-cell monolayers, epithelial cells, and neurons reveal that Cdc42 is a master regulator of polarity in many different systems. Part of this regulation in animals involves the binding of Cdc42 to its

effector, Par6, a polarity protein that functions in nematodes (in which it was first discovered), neurons, and epithelial cells. We explore these polarity pathways in more detail in Chapter 22.

Studies such as these suggest a general model of how cell migration is controlled (Figure 17-44). Signals from the environment are transmitted to Cdc42, which orients the cell. The oriented cell has high Rac activity at the front, which induces the formation of the leading edge; Rho activity is high in the rear, inducing the assembly of contractile structures and activating the myosin-II-based contractile machinery. It is important to notice that different regions of the cell have different levels of active Cdc42, Rac, or Rho, so the amount of these regulators are controlled locally within the cell. Part of this spatial regulation occurs because some small G proteins can work antagonistically. For example, active Rho can stimulate pathways that lead to the inactivation of Rac. This process might help ensure that no leading-edge structures form at the rear of the cell.

FIGURE 17-44 Contributions of Cdc42, Rac, and Rho to cell movement. The overall polarity of a migrating cell is controlled by Cdc42, which is activated at the front of a cell. Cdc42 activation leads to active Rac in the front of the cell, which generates the leading edge, and active Rho at the back of the cell, which causes myosin II activation and contraction. Active Rho inhibits Rac activation, ensuring the asymmetry of the two active G-proteins.

Migrating Cells Are Steered by Chemotactic Molecules

Under certain conditions, extracellular chemical cues guide the migration of a cell in a particular direction. In some cases, the movement is guided by insoluble molecules in the underlying substratum, as in the wounded-cell monolayer assay described above. In other cases, the cell senses soluble molecules and follows

them, along a concentration gradient, to their source — a process known as **chemotaxis**. For example, leukocytes are guided toward an infection by a tripeptide that is released by many bacterial cells (Figure 17-45). In another example, during the development of skeletal muscle, a secreted protein signal called *scatter factor* guides the migration of myoblasts to the proper locations in limb buds. One of the best studied examples of chemotaxis is the migration of *Dictyostelium* amoebae during their starvation response. When these soil amoebae are stressed, they begin to secrete cAMP, which is an extracellular chemotactic agent in this organism. Other *Dictyostelium* cells move up the cAMP concentration gradient toward its source (see Figure 17-45). Thus the amoebae move toward one another, aggregate into a migratory slug, and then differentiate into a fruiting body in which starvation-resistant spores are formed.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 17-45 Chemotactic molecules guide migrating cells by signaling the actin cytoskeleton. *Dictyostelium* cells migrate toward a pipette of cAMP (left), and human neutrophils (a type of leukocyte) migrate toward a pipette of fMLP (formylated Met-Leu-Phe), a chemotactic peptide produced by bacteria (*right*). In the lower two panels are individual chemotaxing *Dictyostelium* and neutrophil cells, which look remarkably similar, despite about 800 million years of evolution separating them.

[Republished with permission from Elsevier, from C. A. Parent, 2004, "Making All The Right Moves: Chemotaxis in Neutrophils and *Dictyostelium*," *Curr. Opin. Cell Biol.* **16**(1):4–13; permission conveyed through Copyright Clearance Center, Inc.]

Despite the variety of different chemotactic molecules — sugars, peptides, cell metabolites, cell-wall or membrane lipids — they all work through a common and familiar mechanism: binding to cell-surface receptors, activation of intracellular signaling pathways, and remodeling of the cytoskeleton through the activation or inhibition of various actin-binding proteins. What is quite amazing is that just a 2 percent difference in the concentration of chemotactic molecules between the front and back of the cell is sufficient to induce directed cell migration (see Classic Experiment 17-2). Equally amazing is the finding that the internal signal transduction pathways used in chemotaxis have been conserved between *Dictyostelium* amoebae and human leukocytes despite almost a billion years of evolution (Figure 17-45).

KEY CONCEPTS OF SECTION 17.7

Cell Migration: Mechanism, Signaling, and Chemotaxis

- Cell migration involves the extension of an actin-rich leading edge at the front of the cell, the formation of focal adhesions that move backward with respect to the cell, and their subsequent release, combined with rear contraction to push the cell forward (see Figure 17-38).
- Cell migration also involves a directed endocytic cycle, taking membrane and adhesion molecules from the rear of the cell and inserting them at the front.
- The assembly and function of actin filaments is controlled by signaling pathways through small GTP-binding proteins of the Rho family. Cdc42 regulates overall polarity and the formation of filopodia, Rac regulates actin network formation through the $\mathrm{Arp2/3}$ complex, and Rho regulates actin filament formation by formins as well as contraction through regulation of myosin II (see Figure 17-42).
- Chemotaxis, the directed movement of cells toward extracellular chemical cues, involves signaling pathways that contribute to the regulation of the actin cytoskeleton

and direction of cell migration.

Review the Concepts

1. Three systems of cytoskeletal filaments exist in most eukaryotic cells. Compare them in terms of composition, function, and structure.
2. Actin filaments have a defined polarity. What is filament polarity? How is it generated at the subunit level? How is filament polarity detectable?
3. In cells, actin filaments form bundles or networks. How do cells form such structures, and what specifically determines whether actin filaments will form a bundle or a network?
4. Much of our understanding of actin assembly in the cell is derived from experiments using purified actin in vitro. What techniques can be used to study actin assembly in vitro? Explain how each of these techniques works. Which of these techniques would tell you whether the mass of actin filaments is made up of many short actin filaments or fewer longer filaments?
5. The predominant forms of actin inside a cell are ATP–G-actin and ADP–F-actin. Explain how the interconversion of the nucleotide state is coupled to the assembly and disassembly of actin subunits. What would be the consequence for actin filament assembly/disassembly if a

mutation prevented actin's ability to bind ATP? What would be the consequence if a mutation prevented actin's ability to hydrolyze ATP?

6. Actin filaments at the leading edge of a crawling cell are believed to undergo treadmilling. What is treadmilling, and what accounts for this assembly behavior?
7. Although purified actin can assemble reversibly in vitro, various actin-binding proteins regulate the assembly of actin filaments in the cell. Predict the effect on a cell's actin cytoskeleton if function-blocking antibodies against each of the following were independently microinjected into cells: profilin, thymosin-β_4, CapZ, and the Arp2/3 complex.
8. Predict how actin would polymerize on a myosin-decorated short actin filament in the presence of CapZ, tropomodulin, or profilin-actin.
9. Compare and contrast the ways in which formin and WASp are activated and explain how each stimulates actin filament formation.
10. There are at least 20 different types of myosin. What properties do all types share, and what makes them different? Why is myosin II the only myosin capable of producing contractile force?
11. The ability of myosin to walk along an actin filament may be observed with the aid of an appropriately equipped microscope. Describe how such assays are typically performed. Why is ATP required in these assays? How can such assays be used to determine the direction of myosin movement or the force produced by myosin?

12. Contractile bundles occur in nonmuscle cells; these structures are less organized than the sarcomeres of muscle cells. What is the purpose of nonmuscle contractile bundles? Which type of myosin is found in contractile bundles?
13. How does myosin convert the chemical energy released by ATP hydrolysis into mechanical work?
14. Myosin II has a duty ratio of 10 percent, and its step size is 8 nm. In contrast, myosin V has a much higher duty ratio (about 70 percent) and takes 36-nm steps as it walks down an actin filament. What differences between myosin II and myosin V account for their different properties? How do the different structures and properties of myosin II and myosin V reflect their different functions in cells?
15. Contraction of both skeletal and smooth muscle is triggered by an increase in cytosolic Ca^{2+}. Compare the mechanisms by which each type of muscle converts a rise in Ca^{2+} concentration into contraction.
16. Phosphorylation of myosin light-chain kinase (MLC kinase) by protein kinase A (PKA) inhibits MLC kinase activation by Ca^{2+}/calmodulin. Drugs such as albuterol bind to the β-adrenergic receptor, which causes a rise in cAMP in cells and activation of PKA. Explain why albuterol is useful for treating the severe contraction of the smooth muscle cells surrounding airway passages involved in an asthma attack.
17. Several types of cells use the actin cytoskeleton to power their locomotion across surfaces. How are different assemblies of actin filaments involved in locomotion?

18. To move in a specific direction, a migrating cell must use extracellular cues to establish which portion of the cell will act as the front and which will act as the back. Describe how small GTPase proteins appear to be involved in the signaling pathways used by migrating cells to determine direction of movement.
19. Cell motility has been described as being like the motion of tank treads. At the leading edge, actin filaments form rapidly into bundles and networks that make protrusions and move the cell forward. At the rear, cell adhesions are broken and the tail end of the cell is brought forward. What provides the traction for moving cells? How does cell-body translocation happen? How are cell adhesions released as cells move forward?

18.7 Intermediate Filaments
18.8 Coordination and Cooperation Between Cytoskeletal Elements

As we learned in the previous chapter, three types of filaments make up the cytoskeleton in an animal cell: microfilaments, microtubules, and intermediate filaments. Why have these three distinct types of filaments evolved? It seems likely that their physical properties are suited to different functions. In Chapter 17, we described how actin microfilaments are often cross-linked into networks or bundles to form mechanically strong yet flexible and dynamic structures and to serve as tracks for the many different classes of myosin motors. Similarly, **microtubules** are stiff tubes that can exist as a single structure, extending up to 20 μm in cells, or in bundled arrangements such as those seen in specialized cell-surface structures like cilia and flagella. As a consequence of their

tubular design, microtubules are able to generate pulling and pushing forces without buckling, a property that allows single tubules to extend long distances within a cell and bundles to slide past each other, as occurs in flagella and in the mitotic spindle. Microtubules' ability to extend long distances in the cell, together with their intrinsic polarity due to the same orientation of subunits along a microtubule, is exploited by microtubule-dependent motors, which use them as tracks for long-range transport of organelles. Microtubules can be highly dynamic — assembling and disassembling rapidly from their ends — and can thus provide the cell with the flexibility to alter microtubule organization as needed.

In contrast to microfilaments and microtubules, **intermediate filaments** have great tensile strength and have evolved to withstand much larger stresses and strains. With properties akin to strong molecular ropes, they are ideally suited to endow both cells and tissues with structural integrity and to contribute to cellular organization. Intermediate filaments do not have an intrinsic polarity as microfilaments and microtubules do, so it is not surprising that there are no motor proteins that use intermediate filaments as tracks. Although we discuss microtubules and intermediate filaments together in this chapter — and although their localization in the cytosol can look superficially quite similar — we will see that their dynamics and functions are very different. A summary of the similarities and differences among these three filament systems is shown in Figure 18-1.

FIGURE 18-1 Overview of the physical properties and functions of the three filament systems in animal cells. (a) Biophysical and biochemical properties (orange) and biological properties (green) are shown for each filament type. The micrographs (b–d) show examples of each filament type in a particular cellular context, but note that microtubules also make up other structures, and that intermediate filaments also line the inner surface of the nucleus. (b) Cultured cells stained for actin (green) and sites of actin attachment to the substratum (orange). (c) Localization of microtubules (green) and the Golgi complex (yellow). Notice the central location of the Golgi complex, which is collected there by transport along microtubules. (d) Localization of cytokeratins (red), a type of intermediate

filament, and a component of desmosomes (yellow) in epithelial cells. Cytokeratins from individual cells are attached to each other through the desmosomes.

This chapter covers five main topics. First, we discuss the structure and dynamics of microtubules and their motor proteins. Second, we examine how microtubules and their motors contribute to the movement of cilia and flagella. Third, we discuss the role of microtubules in the mitotic spindle — a molecular machine that has evolved to accurately segregate duplicated chromosomes. Fourth, we explore the roles of the different classes of intermediate filaments that provide structure to the nuclear envelope as well as strength and organization to cells and tissues. Although we consider microtubules, microfilaments, and intermediate filaments individually, the three filament systems do not act independently of one another, and we consider some examples of this interdependence in the last section of the chapter.

18.1 Microtubule Structure and Organization

In the early days of electron microscopy, cell biologists noted long tubules in the cytoplasm that they called *microtubules*. Morphologically similar microtubules were seen making up the fibers of the mitotic spindle, as components of axons, and as the structural elements in cilia and flagella (Figure 18-2a, b). Careful examination of single microtubules from various sources in transverse section indicated that they were all made up of 13 longitudinal repeating units (Figure 18-2c), now called *protofilaments*, suggesting that these various microtubules shared a common structure. Microtubules purified from brain were found to consist of a major protein, **tubulin**, together with associated proteins. Purified tubulin alone can assemble into a microtubule under favorable conditions, proving that tubulin is the structural component of the microtubule. Associated proteins help mediate the assembly, dynamics, and function of microtubules. In this section, we consider the general structure and organization of microtubules before turning to a more detailed discussion of their dynamics and regulation in Sections 18.2 and 18.3.

FIGURE 18-2 Microtubules are found in many different locations, and all have similar structures. Chrétien, 1998, "Relationship Between Moiré Patterns, Tubulin Shape, and Microtubule Polarity," *Cytoskeleton* **40**(1):38–43; permission conveyed through Copyright Clearance Center, Inc.]

Microtubule Walls Are Polarized Structures Built from αβ-Tubulin

Dimers

Tubulin isolated in a pure and soluble form consists of two closely related subunits called *α-* and *β-tubulin*, each with a molecular weight of about 55,000 Da. The building block of a microtubule is an αβ-tubulin dimer. Genomic analyses reveal that genes encoding α- and β-tubulins are present in all eukaryotes and that the number of genes has expanded considerably in multicellular organisms. For example, budding yeast has two genes specifying α-tubulin and one for β-tubulin, whereas the soil nematode *Caenorhabditis elegans* has nine genes encoding α-tubulin and six for β-tubulin. In addition to α- and β-tubulin, all eukaryotes also have genes specifying a third tubulin, γ-tubulin, which is involved in microtubule assembly, as we will see shortly. Additional isoforms of tubulin have also been discovered that are present only in organisms that possess cellular structures called centrioles and basal bodies, suggesting that these tubulin isoforms are important for those structures. As we'll learn in this chapter, centrioles and basal bodies are specialized structures that nucleate and organize microtubule assembly.

The α- and β-subunits of the tubulin dimer can each bind one molecule of GTP (Figure 18-3a). The GTP in the α-tubulin subunit is never hydrolyzed and is trapped by the interface between the α- and β-subunits. By contrast, the GTP-binding site on the β-subunit is at the surface of the dimer. GTP bound by the β-subunit can be hydrolyzed, and the resulting GDP can be exchanged for free GTP.

Under appropriate conditions, soluble tubulin dimers can assemble into microtubules (Figure 18-3b). As we saw in Chapter 17 for the polymerization of actin, ATP–G-actin is preferentially added to one end of the filament, designated the (+) end because it is the end favored for assembly. Once incorporated into the filament, the bound ATP is hydrolyzed to ADP and P_i. In a similar manner, tubulin dimers in which the β-subunit has bound GTP are added preferentially to one end of the microtubule, also designated the (+) end. As we will see, the GTP is hydrolyzed once tubulin is incorporated into the microtubule and this has dramatic effects on the behavior of the microtubule (+) end.

FIGURE 18-3 Structure of tubulin dimers and their organization into microtubules. (a) Ribbon diagram of the tubulin dimer. The GTP bound to the α-tubulin monomer is nonexchangeable, whereas the GDP bound to the β-tubulin monomer is exchangeable with free GTP. (b) The organization of tubulin subunits in a microtubule. The dimers are aligned end to end into protofilaments, which pack side by side to form the wall of the microtubule. The protofilaments are slightly staggered so that α-tubulin in one protofilament is in contact with α-tubulin in the neighboring protofilaments, except at the seam, where an α-subunit contacts a β-subunit. The microtubule displays a structural polarity in that subunits are added preferentially at the end where β-tubulin monomers are exposed. This end of the microtubule is known as the (+) *end*.

[Part (a) Data from E. Nogales et al., 1998, *Nature* **391**:199, PDB 1D 1tub.]

A microtubule is composed of 13 laterally associated protofilaments, which form a tubule whose external diameter is about 25 nm (see Figure 18-3b). Each of the 13 protofilaments is a string of αβ-tubulin dimers, longitudinally arranged so that the subunits alternate along a protofilament, with each subunit type repeating every 8 nm. Because the αβ-tubulin dimers in a protofilament are all oriented in the same way, each protofilament has an α-subunit at one end and a β-subunit at the other — thus the protofilaments have an intrinsic **polarity**. In a microtubule, all the laterally associated protofilaments have the same polarity, so the microtubule also has an overall polarity. The end with exposed β-subunits is the (+) end, while the end with exposed α-subunits is the (−) end. In microtubules, the heterodimers in adjacent protofilaments are staggered slightly, forming tilted rows of α- and β-tubulin monomers in the microtubule wall. If you follow a row of β-subunits, for example, spiraling around a microtubule for one full turn, you will end up precisely three subunits up the protofilament, abutting an α-subunit. Thus all microtubules have a single longitudinal *seam*, where an α-subunit in one protofilament meets a β-subunit in the adjacent protofilament.

Most microtubules in a cell consist of a simple tube, a *singlet* microtubule, built from 13 protofilaments. In rare cases, singlet microtubules contain more or fewer protofilaments. For example, certain microtubules in the neurons of nematode worms contain 11 or 15 protofilaments. In addition to this simple singlet structure,

doublet or *triplet* microtubules are found in specialized structures such as cilia and flagella (doublet microtubules) and centrioles and basal bodies (triplet microtubules), structures we will explore later in the chapter. Each doublet or triplet contains one complete 13-protofilament microtubule (called the *A tubule*) and one or two additional tubules (B and C) consisting of 10 protofilaments each (Figure 18-4).

FIGURE 18-4 Singlet, doublet, and triplet microtubules. In cross section, a typical microtubule, a singlet, is a simple tube built from 13 protofilaments. In a doublet microtubule, an additional set of 10 protofilaments forms a second tubule (B) by fusing to the wall of a singlet (A) microtubule. Attaching another 10 protofilaments to the (B) tubule of a doublet microtubule creates a (C) tubule and a triplet structure.

Microtubules Are Assembled from MTOCs to Generate Diverse Configurations

Once tubulin had been identified as the major structural component of microtubules, antibodies to tubulin could be generated and used in immunofluorescence microscopy to localize microtubules in cells (Figure 18-5a, b). This approach, coupled with electron microscopy, revealed that microtubules are assembled from specific sites in the cell.

FIGURE 18-5 Microtubules are assembled from microtubule organizing centers (MTOCs). (a–b) The distribution of microtubules in cultured cells, as seen by immunofluorescence microscopy using antibodies to tubulin, in an interphase cell (a) and a cell in mitosis (b). (c–f) Diagrams of the distributions of microtubules in various cells and structures. All of these microtubules are assembled from distinct MTOCs. (c) In an interphase cell, the MTOC is called a centrosome (the nucleus is indicated by a blue oval). (d) In a mitotic cell, the two MTOCs are called *spindle poles* (the chromosomes are shown in blue). (e) In a neuron, microtubules in both axons and dendrites are assembled from an MTOC in the cell body and then released from it. (f) The microtubules that make up the shaft of a cilium or flagellum are assembled from an MTOC known as a basal body. The polarity of microtubules is indicted by (+) and (−).

Spontaneous nucleation of microtubules is such an energetically unfavorable reaction that it does not play a significant role in microtubule assembly in vivo. Rather, all microtubules are nucleated from structures known as **microtubule-organizing centers, or MTOCs**.

The **centrosome** is the main MTOC in animal cells. During interphase, the centrosome is generally located near the nucleus, producing an array of microtubules with their (+) ends radiating toward the cell periphery (Figure 18-5c). In most cases, the (−) end of the microtubule stays anchored in the centrosome. This radial array provides tracks for microtubule-based motor proteins to organize and transport membrane-bounded compartments, such as those constituting the secretory and endocytic pathways. During mitosis, cells reorganize their microtubules to form a bipolar spindle extending from two centrosomes, also known as *spindle poles*, that can accurately segregate copies of the duplicated chromosomes (Figure 18-5d). Neurons, in another example, have long processes called *axons*, in which organelles are transported in both directions along microtubules (Figure 18-5e). The microtubules in axons, which can be as long as 1 m, are not continuous and have been released from the MTOC, but nevertheless all have the same polarity. The microtubules in shorter processes, called *dendrites*, have mixed polarity, although the functional significance of this difference is not clear. In cilia and flagella (Figure 18-5f), microtubules are assembled from an MTOC called a **basal body**. As

we mention later, plants do not have centrosomes and basal bodies; they use other mechanisms to nucleate the assembly of microtubules.

Electron microscopy shows that each centrosome in an animal cell consists of a pair of orthogonally arranged cylindrical **centrioles** surrounded by amorphous material called **pericentriolar material** (Figure 18-6a). Centrioles, which are about 0.5 μm long and 0.2 μm in diameter, are highly organized and stable structures that consist of nine triplet microtubules (Figure 18-6b, c). The centrioles themselves do not nucleate the cytoplasmic microtubule array. Instead, factors in the pericentriolar material do. A critical component is the *γ-tubulin ring complex (γ-TuRC)* (Figure 18-6b and Figure 18-7), which is located in the pericentriolar material and consists of many copies of γ-tubulin associated with several other proteins. The γ-TuRC acts as a helical template to bind αβ-tubulin dimers for the formation of a new microtubule, whose (−) end is associated with γ-TuRC and whose (+) end is free for further assembly.

FIGURE 18-6 Structure of centrosomes. (a) Thin section of an animal-cell centrosome showing the two centrioles at right angles to each other, surrounded by pericentriolar material (arrows). (b) Diagram of a centrosome showing the mother and daughter centrioles, each of which consists of nine linked triplet microtubules, embedded in pericentriolar material that contains γ-TuRC nucleating structures. The mother centriole is distinct from the daughter as it has distal appendages (blue spheres). (c) A tomographic image of a section through a daughter centriole of the alga *Chlamydomonas*. A protein called *Sas6* can self-assemble into a ninefold symmetrical cartwheel structure to serve as a template for the daughter centriole (purple structure). It is later removed as the centriole matures. (d) Immunofluorescence micrograph showing the microtubule array (green) in a cultured animal cell and the location of the MTOC, using an antibody to a centrosomal protein (yellow).

Cell Biol.* **6**:743–748; permission conveyed through Copyright Clearance Center, Inc. Part (c) Data from P. Guichard et al., 2013, *Curr. Biol.* **23**:1620, EMD-2329 and EMD-2330.]

Basal bodies have a structure similar to centrioles and are the MTOCs found at the base of cilia and flagella. The A and B tubules of their triplet microtubules provide a template for the assembly of the microtubules making up the core structure of cilia and flagella. Later, we discuss the structure of basal bodies in the context of cilia and flagella.

Recent work has uncovered an additional mechanism for the nucleation of microtubules in animal cells, also involving γ-TuRC. A protein complex called the *augmin complex*, consisting of eight polypeptides, can bind to the sides of existing microtubules, then recruit γ-TuRC and nucleate the assembly of new ones (Figure 18-7c). As we discuss in a later section, the augmin complex contributes to microtubule assembly in the mitotic spindle.

FIGURE 18-7 The γ-tubulin ring complex (*γ*-TuRC) that nucleates microtubule assembly. (a) Immunofluorescence micrograph in which microtubules assembled in vitro are labeled green and a component of the γ-TuRC is labeled red, showing that it is located specifically at one end of the microtubule. (b) Model of how γ-TuRC nucleates assembly of a microtubule by forming a template corresponding to the (−) end. (c) Diagram of how augmin can bind both γ-TuRC and the side of an existing microtubule to nucleate assembly of a branched microtubule.

KEY CONCEPTS OF SECTION 18.1

Microtubule Structure and Organization

- Tubulin is the major structural component of microtubules (see Figure 18-3). Microtubule-associated proteins (MAPs) associate with tubulin and help mediate the assembly, dynamics, and function of microtubules.
- Free tubulin exists as a dimer in which the α-subunit contains a trapped and nonhydrolyzable GTP and the β-subunit binds an exchangeable and hydrolyzable GTP.
- αβ-Tubulin assembles into microtubules, each of which is made up of 13 laterally associated protofilaments, with an α-subunit exposed at the (−) end and a β-subunit at the (+) end of each protofilament.
- In cilia, flagella, centrioles, and basal bodies, doublet and triplet microtubules exist in which the additional microtubules have 10 protofilaments (see Figure 18-4).
- All microtubules are nucleated from microtubule-organizing centers (MTOCs), and many remain anchored with their (−) ends there. Thus the end away from the MTOC is always the (+) end.
- The centrosome is the MTOC that nucleates the radial array of microtubules in interphase animal cells. Two centrosomes, or spindle poles, are the MTOCs that nucleate the microtubules of the mitotic spindle in animal cells. Basal bodies are the MTOCs that assemble the microtubules of cilia and flagella (see Figure 18-5).
- Centrosomes consist of two centrioles and the surrounding pericentriolar material, which contains the γ-TuRC microtubule-nucleating complex (see Figures 18-6 and 18-

7).

18.2 Microtubule Dynamics

Microtubules are dynamic structures that can assemble or disassemble rapidly at their ends. Their lifetimes can vary enormously, averaging less than 1 minute for cells in mitosis and about 5–10 minutes for the microtubules that make up the radial array seen in interphase animal cells. Microtubule lifetime is longer in axons and much longer in cilia and flagella. To see how these differences occur, we will look at the dynamic properties of microtubules and how these properties contribute to their cellular organization.

Individual Microtubules Exhibit Dynamic Instability

Early experiments revealed that most microtubules in animal cells disassemble when the cells are cooled to 4 °C and reassemble when the cells are warmed to 37 °C. Researchers realized that this intrinsic property of microtubules could be exploited to purify their components. Since brain tissue is rich in microtubules, soluble extracts of pig brains were prepared at 4 °C; these clarified extracts were then warmed to 37 °C to induce microtubule assembly. The assembled microtubules were collected into a pellet by centrifugation, separated from the supernatant, and then disassembled by adding buffer at 4 °C. After another cycle of

assembly by warming, collection, and disassembly by cooling, researchers recovered *microtubular protein*, a collective term for αβ-tubulin and **microtubule-associated proteins (MAPs)**. They were then able to fractionate the microtubular protein into pure αβ-tubulin and MAPs to study their behaviors separately. Investigators found that polymerization of dimeric αβ-tubulin into microtubules can be catalyzed by the presence of the MAPs.

Research on the bulk polymerization properties of microtubular proteins in solution revealed two important things. First, for assembly to occur, the αβ-tubulin concentration must be above the *critical concentration* (C_c), just as we saw for actin polymerization (see Figure 17-8). Second, at αβ-tubulin concentrations higher than C_c, tubulin dimers are added faster to one end of the microtubule than to the other (Figure 18-8). As with F-actin assembly, the preferred end for assembly, which is the end with β-tubulin exposed, is designated the (+) end. The (−) end has α-tubulin exposed (see Figure 18-3b).

Courtesy of Gary G. Borisy.

EXPERIMENTAL FIGURE 18-8 Microtubules grow preferentially at the (+) end. A fragment of a microtubule bundle from a flagellum was used as a nucleus for the in vitro addition of αβ-tubulin. The nucleating flagellar fragment is the thick bundle seen in this electron micrograph, with the newly formed microtubules (MT) radiating from its ends. The greater length of the microtubules at one end,

the (+) end, indicates that tubulin subunits are added preferentially to this end.

When studying the bulk properties of microtubule assembly by raising the temperature of a tubulin solution from 4 °C to 37 °C, a typical curve reflecting nucleation, elongation, and steady state is observed (Figure 18-9a). Although one might assume that all microtubules would behave similarly, when researchers explored the behavior of individual microtubules within a population, they found that this was not the case. Individual microtubule behavior was examined in a simple experiment: microtubules were assembled in vitro and then sheared to break them into shorter pieces whose individual lengths could be analyzed by microscopy. Under these conditions, one might expect all the short microtubules either to grow or to shrink, depending on the free tubulin concentration. However, the investigators found that some of the microtubules grew in length, whereas others shortened very rapidly — thus indicating the existence of two distinct populations of microtubules. Further studies showed that individual microtubules could grow and then suddenly experience a *catastrophe*: an abrupt transition to a shrinking phase during which the microtubule would undergo rapid depolymerization. Moreover, sometimes a depolymerizing microtubule end could go through a *rescue* and begin growing again (Figure 18-9b). Although this phenomenon was first seen in vitro, analysis of fluorescently labeled tubulin microinjected into live cells showed that microtubules in cells also

undergo periods of growth and shrinkage (Figure 18-10). This alternation between growing and shrinking states is known as *dynamic instability*. Thus the dynamic life of a microtubule end is determined by the rate of growth, the frequency of catastrophes, the rate of depolymerization, and the frequency of rescues. As we will see, these four features of microtubule dynamics are controlled in vivo. Since the (−) ends of microtubules in animal cells are generally anchored to an MTOC, this dynamism is most relevant to the (+) end of the microtubule.

FIGURE 18-9 Comparison of the assembly properties of a preparation of bulk tubulin compared with the dynamics of an individual microtubule. (a) When pure tubulin above its C_c is warmed from 4 °C to 37 °C to induce polymerization, typical nucleation, elongation, and steady-state phases are seen. (b) However, when individual microtubules in an assembling population are observed in the light microscope and their lengths plotted at different times, they can be seen to grow and shrink in a process known as *dynamic instability*. Assembly and disassembly each proceed at uniform rates, but there is a big difference between the rate of assembly and that of disassembly, as seen in the different slopes of the lines. Shortening of a microtubule is much more rapid (7 μm/min) than growth (1 μm/min). Notice the abrupt transitions to the shrinkage stage (catastrophe) and to the elongation stage (rescue).

[Data from P. M. Bayley, K. K. Sharma, and S. R. Martin, 1994, in J. S. Hyams and C. W. Lloyd, eds., *Microtubules*, p. 118. New York: Wiley-Liss.]

EXPERIMENTAL FIGURE 18-10 Fluorescence microscopy reveals growth and shrinkage of individual microtubules in vivo. Fluorescently labeled tubulin was microinjected into cultured human fibroblasts. The cells were chilled to depolymerize preexisting microtubules into tubulin dimers and were then incubated at 37 °C to allow repolymerization, which incorporated the fluorescent tubulin into all the cells' microtubules. A region of a cell periphery was viewed in the fluorescence microscope at 0 seconds, 27 seconds later, and 3 minutes 51 seconds later (*left to right panels*). During this period, several microtubules can be seen to have elongated and shortened. The dots labeled *A*, *B*, and *C* mark the positions of the ends of three microtubules.

What is the molecular basis of dynamic instability? If we look carefully at the ends of growing and shrinking microtubules in the electron microscope, we can see that they are quite different. A growing microtubule has a relatively blunt end, whereas a

depolymerizing end has highly curved protofilaments peeling off like rams' horns (Figure 18-11). In fact, the growing microtubule end is not simply a blunt end, but a ragged collection of gently curving protofilaments that then associate laterally to form the cylindrical microtubule with straight protofilaments.

FIGURE 18-11 Dynamic instability depends on the presence or absence of a GTP-β-tubulin cap. Images taken in the electron microscope of frozen samples of a growing microtubule (*upper*) and a shrinking microtubule (*lower*). Notice that the end of the growing microtubule has a blunter end, whereas the end of the shrinking one has curls like a ram's horns. As the diagram shows, a microtubule with several GTP-β-tubulin dimers on the end of each protofilament is strongly favored to grow. However, a microtubule with GDP-β-tubulin at the ends forms highly curved protofilaments and will undergo rapid disassembly. Switches between growing and shrinking phases, called *rescues* and *catastrophes*, can occur, and the rate of switching is regulated by associated proteins.

[E. M. Mandelkow, E. Mandelkow, and R. A. Milligan, 1991, *J. Cell Biol.* **114**(5): 977–991; https://doi.org/10.1083/jcb.114.5.977.]

A simple structural difference accounts for the morphology of these two different classes of microtubule (+) ends. Using a GDP analog, researchers have found that artificially made *single* protofilaments — which are not exposed to lateral interactions — made up of repeating αβ-tubulin dimers containing GDP-β-tubulin are curved, like a ram's horn. However, artificially made single protofilaments made up of αβ-tubulin dimers in which β-tubulin has a bound GTP analog are only slightly curved. The assembling end of a microtubule contains these slightly curved nascent protofilaments, giving rise to the gently curved protofilaments characteristic of growing ends (see Figure 18-11). The gently curved protofilaments containing GTP-β-tubulin then zip up by lateral interactions to form straight protofilaments within the microtubule. Such a growing microtubule is said to have a GTP cap. By contrast, shrinking microtubules with highly curled ends are made up of GDP-β-tubulin. Therefore, if the GTP molecules in the terminal β-tubulins become hydrolyzed on a

microtubule that has stopped growing, a formerly blunt-ended microtubule will curl and a catastrophe will ensue. These relationships are summarized in Figure 18-11.

These results have an additional and fascinating implication, but to understand it we must consider the growing microtubule in more detail. The addition of dimers with GTP-β-tubulin to the (+) end of protofilaments on a growing microtubule will generate the GTP cap on each protofilament. These elongated protofilaments then associate by lateral interactions to become straight and form the microtubule wall. This transition from a curved to straight protofilament induces a strained conformation in the tubulin dimer. The interaction between the β-subunit of one dimer and the α-subunit of the next enhances hydrolysis of GTP in the β-subunit to GDP-P_i. The inorganic P_i is then slowly released. In this way, a growing microtubule has a GTP cap, followed by a region in which β-tubulin has GDP-P_i, followed by the older region that has just GDP-β-tubulin (see Figure 18-11).

As we mentioned above, an *isolated* protofilament containing GDP-β-tubulin is curved along its length, so when it is present in a microtubule, why doesn't it break out and peel away? The lateral protofilament-protofilament interactions in the GTP-β-tubulin cap are sufficiently strong that they do not allow the microtubule to unpeel at its end — and so the protofilaments behind the GTP-β-tubulin cap are constrained from unpeeling (see Figure 18-11). The

energy released by GTP hydrolysis in the subunits behind the cap is stored within the lattice as structural strain waiting to be released when the GTP-β-tubulin cap is lost. This implies that if the GTP-β-tubulin cap is lost, the stored energy can do work if some structure, such as a chromosome, is attached to the disassembling microtubule end. As we will see, this stored energy drives the movement of chromosomes during the anaphase stage of mitosis.

How can a disassembling microtubule suddenly be rescued to grow again? One possible answer to this perplexing problem has been suggested. Using an antibody that recognizes GTP-β-tubulin but not GDP-β-tubulin, researchers have found that islands of GTP-β-tubulin can persist along the length of an assembled microtubule. It seems likely that when a disassembling microtubule encounters one of these GTP-β-tubulin islands, disassembly pauses, and a rescue may be provoked.

Localized Assembly and *Search and Capture* Help Organize Microtubules

We have now presented two major concepts relating to microtubule organization and (+) end dynamics: microtubules are assembled starting from MTOCs, and individual microtubules can undergo dynamic instability. Together, these two processes contribute to the distribution of microtubules in cells.

In an interphase cell growing in culture, microtubules are constantly being nucleated from the centrosome and spreading out, randomly *searching* the cytoplasmic space. The frequency of catastrophes and rescues, together with growth and shrinkage rates, determines the length of each microtubule. If the microtubule is subject to a high catastrophe frequency and a low rescue frequency, it will shrink back to the centrosome and disappear, whereas if it has few catastrophes and is readily rescued, it will continue to grow. If the searching microtubule encounters an appropriate target on a cell structure or organelle, the microtubule end may become attached to that structure. Organelle or cell-structure *capture* by the microtubule can stabilize its (+) end and protect it from catastrophes, whereas unattached microtubules have a greater frequency of disassembly. So the dynamics of the microtubule (+) end is a very important determinant of microtubule life cycle and function. *Search and capture* is part of the mechanism determining the overall organization of microtubules in a cell. Moreover, by changing the rate of nucleation or local microtubule dynamics and capture sites, a cell can rapidly change its overall microtubule distribution. We will see later that this is what happens as cells enter mitosis.

Drugs Affecting Tubulin Polymerization Are Useful

Experimentally and in Treatment of Diseases

The conserved nature of tubulins and their essential role in critical processes such as mitosis make them prime targets for both naturally occurring and synthetic drugs that affect polymerization or depolymerization. The first of these drugs was colchicine (present in extracts of the meadow saffron), which binds tubulin dimers so that they cannot polymerize into microtubules. Since most microtubules are in a dynamic state between dimers and polymers, the addition of colchicine sequesters all free dimers in the cytoplasm, resulting in loss of microtubules due to their natural turnover. Treatment of cultured cells with colchicine for a short time results in the depolymerization of all the cytoplasmic microtubules, leaving the more stable tubulin-containing centrosome (Figure 18-12a). When the colchicine is washed out to allow regrowth of the microtubules, they can be seen to grow from the centrosome, revealing its ability to nucleate the assembly of new microtubules (Figure 18-12b).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 18-12 Microtubules grow from the MTOC. To investigate the assembly of microtubules in vivo, a cultured fibroblast was treated with colchicine until almost all the cytoplasmic microtubules were disassembled. The cell was then stained with antibodies to tubulin and viewed by immunofluorescence microscopy (a). In a separate experiment, the colchicine was washed out to allow reassembly of the microtubules. Panel (b) shows the first stages of reassembly, revealing microtubules growing from the MTOC in the central region above the nucleus (dark area). Note in panel (a) the remaining primary cilium (arrowhead; discussed in Section 18.5) associated with the centrosome, which is not depolymerized by colchicine treatment under these conditions. Note also the fluorescence from the cytoplasm, which is from unpolymerized αβ-tubulin dimers.

[E. M. Mandelkow, E. Mandelkow, and R. A. Milligan, 1991, *J. Cell Biol.* **114**(5):977–991; https://doi.org/10.1083/jcb.114.5.977.]

Colchicine has been used for hundreds of years to relieve the joint pain of acute gout. A famous patient was King Henry VIII of England, who was treated with colchicine to relieve this ailment. A low level of colchicine relieves the inflammation caused in gout by

reducing the microtubule dynamics of white blood cells, rendering them unable to migrate efficiently to the site of inflammation.

In addition to colchicine, a number of other drugs bind the tubulin dimer and restrain it from forming polymers. These drugs include podophyllotoxin (from juniper) and nocodazole (a synthetic drug).

Taxol, a plant alkaloid from the Pacific yew tree, binds microtubules and stabilizes them against depolymerization. Because taxol stops cells from dividing by inhibiting mitosis, it has been used to treat some cancers, such as those of the breast and ovary, where the cells are especially sensitive to the drug. ■

KEY CONCEPTS OF SECTION 18.2

Microtubule Dynamics

- Individual microtubule (+) ends can undergo dynamic instability, showing alternating periods of growth or rapid shrinkage (see Figure 18-10).
- Most of the β-tubulin in microtubules contains bound GDP. In growing microtubules, the (+) ends have a cap of many dimers containing GTP-β-tubulin, resulting in slightly splayed ragged protofilament ends. Shrinking microtubules have lost the cap, causing the protofilaments at the end, containing GDP-β-tubulin, to peel outward and disassemble (see Figure 18-11).
- Growing microtubules store the energy derived from GTP hydrolysis in the microtubule lattice, so they have the potential to do work when disassembling.
- Microtubules assembled from the centrosome and exhibiting dynamic instability can search the cytoplasm for structures or organelles with appropriate targets and capture them, which results in stabilization of the microtubule (+) end. In this way, assembly coupled with search and capture can contribute to the overall distribution of microtubules in a cell.

18.3 Regulation of Microtubule Structure and Dynamics

The regulation of microtubule structure and dynamics is critical for proper cell function. As we will see later in this chapter, microtubules are the major organizers of organelles in animal cells, and the stability and dynamics of microtubules are tailored for the specific function of the cell at any given time. For example, the dynamics of microtubules increase dramatically as a cell enters mitosis to allow the cell to build the mitotic spindle.

The wall of a microtubule is built from αβ-tubulin dimers, and highly purified αβ-tubulin will assemble in vitro into microtubules. Assembly of microtubules in vitro is greatly enhanced by the presence of certain microtubule-associated proteins (MAPs). MAPs regulate microtubule dynamics in a number of ways. Broadly, some stabilize microtubules, other MAPs destabilize them, and a third group of MAPs alters the growth properties of microtubules. We discuss the various examples of MAPs in this section, which are summarized in Table 18-1.

TABLE 18-1 • Summary of the Microtubule-Associated Proteins (MAPs) Discussed in This Section

Name	Function
MAP2, MAP4, Tau	Stabilizing

EB1	+TIP enhances catastrophes
XMAP215	+TIP promotes (+) end growth
CLASP	+TIP suppresses (+) end catastrophes
Kinesin-13	Promotes end disassembly
Op18/Statmin	Promotes (+) end disassembly
Katanin	AAA ATPase severing

Microtubules Are Stabilized by Side-Binding Proteins

Several classes of proteins stabilize microtubules, many of which show cell-type-specific expression. Among the best-studied MAPs are members of the tau family of proteins, which includes tau itself as well as proteins called *MAP2* and *MAP4*. Tau and MAP2 are neuronal proteins, while MAP4 is expressed by other cell types and is generally not present in neurons. These proteins have a modular design with two key domains. The first domain consists of a positively charged 18-residue sequence, repeated three to four times, that binds to the negatively charged microtubule surface. The second domain projects outward at a right angle from the microtubule (Figure 18-13b). Tau proteins stabilize microtubules and also act as spacers between them. MAP2 is found only in dendrites of neurons, where it forms fibrous cross-bridges between

microtubules and links microtubules to intermediate filaments. Tau, which is much smaller than most other MAPs, is present in both axons and dendrites. The basis for this specificity is still a mystery.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 18-13 Spacing of microtubules depends on the length of the projection domains of microtubule-associated proteins. (a) Insect cells transfected to express MAP2, which has a long arm, or to express tau protein, which has a short arm, grow long axon-like processes. These electron micrographs show cross sections through the processes induced by the expression of MAP2 (*left*) and tau (*right*) in transfected cells. Note that the spacing between microtubules (MTs) in MAP2-containing cells is greater than in tau-containing cells. Both cell types contain approximately the same number of microtubules, but the effect of MAP2 is to enlarge the caliber of the axon-like process. (b) Diagrams of association between microtubules and MAPs. Note the difference between the lengths of the projection domains in MAP2 and in tau.

[Part (a) Reprinted by permission from Nature Publishing Group, from J. Chen et al., 1992, "Projection Domains of MAP2 and Tau Determine Spacings Between Microtubules in Dendrites and Axons," *Nature*, **360**(6405):674–676; permission conveyed throght Copyright Clearance Center, Inc.]

When stabilizing MAPs coat the outer wall of a microtubule, they can increase the growth rate of microtubules or reduce catastrophe frequency. In many cases, the activity of the MAPs is regulated by the reversible phosphorylation of their projection domains. Phosphorylated MAPs are unable to bind to microtubules; thus phosphorylation promotes microtubule disassembly. For example, microtubule-affinity-regulating kinase (MARK/Par-1) is a key modulator of tau proteins. Some MAPs, including MAP4, are also phosphorylated by a cyclin-dependent kinase (CDK) that plays a major role in controlling the activities of proteins in the course of the cell cycle (see Chapter 19).

+TIPs Regulate the Properties and Functions of the Microtubule (+) End

In addition to the side-binding MAPs, MAPs that associate with a region near the (+) end of microtubules have been identified. In many cases, they associate only with (+) ends that are growing (Figure 18-14a, b). The MAPs in this class are known as *+TIPs*, for plus-end tracking proteins. The best studied of these is between the +TIP called *EB1* (end binding-1) and the related *EB3* and a growing microtubule (+) end. High-resolution microscopy has revealed that EB1 associates with the microtubule tip just behind the GTP-β-tubulin-containing cap, in the region containing GDP-P_i-β-tubulin (see Figure 18-11). Binding of EB1 induces a twist in the tubulin subunits that is thought to transmit a long-range mechanical signal to enhance GTP hydrolysis in the cap. Thus at least in some in vitro studies EB1 is a destabilizer of microtubules leading to a higher rate of catastrophe (Figure 18-14c). Some +TIPs associate with the (+) end either by binding EB1 or by requiring EB1 for their association with the (+) end, and are generally said to be "hitchhiking" on EB1 (Figure 18-14d).

EXPERIMENTAL FIGURE 18-14 The +TIP protein EB1 associates near the (+) ends of microtubules. (a) A cultured cell stained with antibodies to tubulin (red) and the +TIP protein EB1 (green). EB1 is enriched in the region of the microtubule (+) end. (b) Edge of a live cell expressing EB3-GFP (green) and mCherry-α-tubulin (red). EB3, which is closely related to EB1, is found very close to the end of some microtubules. (c) EB3-GFP selectively associates with growing microtubules, as seen in this so-called kymograph. In this figure, the dynamics of a single microtubule (red) and EB3 (green) in a live cell like that shown in part (b) is followed by taking the same region from sequential frames of a movie and lining them up top to bottom. At the top, one sees the start of the movie with the microtubule capped by EB3. Moving down the figure, one can track the dynamics of the microtubule over time as it grows and shrinks. When the microtubule grows, it remains capped by EB3. When microtubule growth pauses or the microtubule shrinks, EB3 is no longer associated with the end, but it becomes reassociated when growth resumes. A diagrammatic summary of the microtubule dynamics overlies the kymograph. (d) A possible mechanism for EB1 binding to a growing microtubule and “hitchhiking” by other proteins on EB1.

Other +TIPs, that bind independently of EB1, can promote microtubule growth either by enhancing assembly or by suppressing catastrophes. For example, a protein called *XMAP215* contains five so-called TOG domains. These domains have the ability to bind free αβ-tubulin dimers as well as the gently curved regions of protofilaments at the growing end of a microtubule. By binding to the growing end and bringing more αβ-tubulin dimers there, XMAP215 effectively increases the local αβ-tubulin concentration to enhance microtubule assembly (Figure 18-15a). Another class of proteins, called *CLASPs*, have related TOG domains but do not enhance assembly. Instead, they bind to the gently curved growing end and suppress catastrophes (Figure 18-15b). Another function of +TIPs is to link the microtubule (+) end to other cellular structures, such as the cell cortex, F-actin, and as we will see later during our discussion of mitosis, chromosomes; a key feature of this dynamic system is that when a +TIP at the end of a searching microtubule encounters an appropriate target, the microtubule can become captured and stabilized. Yet other +TIPs link microtubule (+) ends to membranes; for example, linkage to the endoplasmic reticulum transmembrane protein *STIM* promotes microtubule-dependent extension of the tubular endoplasmic reticulum.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 18-15 Proteins that regulate the ends of microtubules. (a) The protein XMAP15 has five TOG domains, some of which bind the gently curved protofilaments of a growing microtubule end, whereas others bind αβ-tubulin dimers to enhance gowth. (b) CLASP also has TOG domains that stabilize the

ends of microtubules to suppress catastrophes. (c) A member of the kinesin-13 family enriched at a microtubule end can enhance the disassembly of that end. [Although depolymerization of the (+) end is shown, kinesin-13 can also depolymerize the (−) end.] These proteins are ATPases, and ATP enhances their activity by dissociating them from the αβ-tubulin dimer. (d) Op18/stathmin binds selectively to curved protofilaments and enhances their dissociation from a microtubule end.

Other End-Binding Proteins Also Promote Microtubule Disassembly

Various mechanisms for microtubule destabilization are known. One of these involves the kinesin-13 family of proteins. As we will see in Section 18.4, most kinesins are molecular motors, but the kinesin-13 proteins are a distinct class of kinesin that bind to and curve the end of the tubulin protofilaments into the GDP-β-tubulin conformation. They then facilitate the removal of terminal tubulin dimers, thereby greatly enhancing the frequency of catastrophes (Figure 18-15c). They act catalytically in the sense that they need to hydrolyze ATP to remove sequential terminal tubulin dimers.

Another protein, known as *Op18/stathmin*, also enhances the rate of catastrophes. It was originally identified as a protein highly overexpressed in certain cancers; hence part of its name (Oncoprotein 18). Op18/stathmin is a small protein that binds two tubulin dimers in a curved, GDP-β-tubulin-like conformation (Figure 18-15d). It may function by enhancing the hydrolysis of the GTP in

the terminal tubulin dimer and aiding in its dissociation from the end of the microtubule. As might be expected for a regulator of microtubule ends, it is subject to negative regulation by phosphorylation by a large variety of kinases. In fact, it has been found that Op18/stathmin is inactivated by phosphorylation near the leading edge of a motile cell, which contributes to preferential growth of microtubules toward the front of the cell.

Severing Proteins Also Regulate Microtubule Dynamics

Animals and plants also have microtubule-severing proteins. All microtubule-severing proteins are members of the AAA ATPases, enzymes that have the ability to use the power of ATP hydrolysis to disassemble protein complexes. The first to be isolated was called *katanin* after the Japanese samurai sword. Katanin forms a six-membered ring that can sever a microtubule by literally pulling subunits out of the microtubule, resulting in its destabilization and severing. This results either in more rapid depolymerization of the microtubule, or in the majority of cases, the microtubule is repaired with GTP-tubulin to generate a new growing end. Although microtubule-severing proteins clearly have an important function in animal cells, it has been difficult to pinpoint exactly what that is. However, in plant cells, microtubule severing of cortical microtubules has been clearly documented.

KEY CONCEPTS OF SECTION 18.3

Regulation of Microtubule Structure and Dynamics

- Microtubules can be stabilized by side-binding microtubule-associated proteins (MAPs) (see Figure 18-13).
- Some MAPs, called *+TIPs,* bind selectively to growing (+) ends of microtubules and can alter the dynamic properties of the microtubule or attach components of the cell to the searching (+) end of the microtubule (see Figure 18-14).
- Proteins, such as XMAP15, enhance the growth of microtubule (+) ends, or stabilize them against catastrophes, such as CLASP (see Figure 18-15a, b).
- Microtubule ends can be destabilized by some proteins, such as the kinesin-13 family of proteins and Op18/stathmin, to enhance the frequency of catastrophes (see Figure 18-15c, d).
- MAPs, such as katanin, are AAA ATPases that sever microtubules.

18.4 Kinesins and Dyneins: Microtubule-Based Motor Proteins

Organelles in cells are frequently transported distances of many micrometers along well-defined routes in the cytoplasm and delivered to particular intracellular locations. Diffusion alone cannot account for the rate, directionality, and destinations of such transport processes. Findings from early experiments with fish-scale pigment cells and neurons demonstrated that microtubules function as tracks in the intracellular transport of various types of so-called cargo.

As already discussed, polymerization and depolymerization of microtubules can do work using the energy provided by GTP hydrolysis. In addition, **motor proteins** move along microtubules, powered by ATP hydrolysis. Two families of motor proteins — **kinesins** and **dyneins** — are known to mediate transport along microtubules. In this section, we first discuss the initial evidence for the existence of these motors and then how they work and the roles they perform in interphase cells. In subsequent sections, we discuss their functions in cilia and flagella, and in mitosis.

Organelles in Axons Are Transported Along Microtubules in Both Directions

A neuron must constantly supply new materials — proteins and membranes — to its axon terminal to replenish those lost in the exocytosis of neurotransmitters at the junction (synapse) with another cell (see Chapter 23). Because proteins and membranes are primarily synthesized in the cell body, these materials must be transported down the length of the axon, which can be as long as a meter in some neurons. This movement of materials is accomplished on microtubules, which are all oriented with their (+) ends toward the axon terminal (see Figure 18-5e).

The results of classic experiments, in which radioactive amino acids were microinjected into the dorsal-root ganglia near the spinal cord to allow for their incorporation into proteins in spinal neurons, and the radioactivity then tracked along the axons of those cells, showed that **axonal transport** occurs from the cell body down the axon. Other experiments showed that transport could also occur in the reverse direction, toward the cell body. *Anterograde* transport proceeds from the cell body to the axon terminal and is associated with axonal growth and the delivery of synaptic vesicles. *Retrograde* transport moves recycling membranes from the axon terminal along the axon toward the cell body.

These experiments also revealed that different materials move at different speeds (Figure 18-16). The fastest moving material, consisting of membrane-bound vesicles, has a velocity of about 3 μm/s, or 250 mm/day — requiring about 4 days to travel from a cell

body in your back down an axon that terminates in your big toe. The slowest moving material, comprising tubulin subunits and neurofilaments (the intermediate filaments found in neurons), moves only a fraction of a millimeter per day. Organelles such as mitochondria move down the axon at an intermediate rate.

EXPERIMENTAL FIGURE 18-16 The rate of axonal transport in vivo can be determined by radiolabeling and gel electrophoresis. The cell bodies of neurons in the sciatic nerve are located in dorsal-root ganglia (near the spinal cord). Radioactive amino acids injected into these ganglia in experimental animals are incorporated into newly synthesized proteins, which are then transported down the axon to the synapse. Animals are sacrificed at various times after injection and the dissected sciatic nerve is cut into small segments to see how far radioactively labeled proteins have been transported; these proteins can be identified after gel electrophoresis and autoradiography. The red, blue, and purple dots represent groups of proteins that are transported down the axon at different rates, red most rapidly, purple least rapidly.

Neurobiologists have long made extensive use of the squid giant axon for studying organelle movement along microtubules. Involved in regulating the squid's water propulsion system, the aptly named giant axon can be up to 1 mm in diameter, which is about 100 times wider than the average mammalian axon. Moreover, squeezing the axon like a tube of toothpaste pushes out the cytoplasm (also known as *axoplasm*), which can then be observed by video microscopy. The movement of vesicles along microtubules in this cell-free system requires ATP, moving at a rate similar to that of axonal transport in intact cells, and can proceed in both anterograde and retrograde directions (Figure 18-17). Collectively, these experiments showed that there must be ATP-dependent motors capable of moving cargo along microtubules in anterograde and retrograde directions. Moreover, electron microscopy of squid giant axon cytoplasm showed organelles attached to individual microtubules.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Comp

EXPERIMENTAL FIGURE 18-17 DIC microscopy demonstrates microtubule-based vesicle transport in vitro. Cytoplasm was squeezed from a squid giant axon with a roller onto a glass coverslip. After buffer containing ATP was added to the preparation, it was viewed by differential interference contrast (DIC) microscopy, and the images were recorded on videotape. In the sequential images shown, the two organelles indicated by open and solid triangles move in opposite directions (indicated by colored arrows) along the same filament, pass each other, and continue in their original directions. Elapsed time in seconds appears at the upper-right corner of each video frame.

[Republished with permission from Elsevier, from B. J. Schnapp et al., 1985. "Single Microtubules from Squid Axoplasm Support Bidirectional Movement of Organelles," *Cell*, **40**(2):455–462; permission conveyed through the Copyright Clearance Center, Inc.]

In other experiments, neurofilaments were tagged with green fluorescent protein (GFP) and then injected into cultured cells. The results of these experiments suggest that neurofilaments pause frequently as they move down an axon. Although the peak velocity of neurofilaments is similar to that of fast-moving vesicles, their numerous pauses lower the average rate of transport. These findings suggest that there is no fundamental difference between fast and slow axonal transport.

Kinesin-1 Powers Anterograde Transport of Vesicles Down Axons Toward the (+) Ends of Microtubules

The protein responsible for anterograde organelle transport was first purified from axonal extracts. Researchers found that when they mixed three components — purified organelles from squid axons, an organelle-free cytosolic axonal extract, and taxol-stabilized microtubules — organelles could be seen moving on the microtubules in an ATP-dependent manner. However, if they omitted the axonal extract, the organelles neither bound nor moved along the microtubules. The researchers concluded that the extract contributes a protein that both attaches organelles to a microtubule and transports them along it — that is, a motor protein.

Their strategy for purifying the motor protein was based on additional observations of organelles moving on microtubules. It was known that if ATP was hydrolyzed to ADP, the organelles fell off the microtubules. However, if the nonhydrolyzable ATP analog AMPPNP was added, the organelles remained associated with the microtubules, but did not move. These observations suggested that the motor protein linked the organelles to the microtubules very tightly in the presence of AMPPNP, but when AMPPNP was replaced by ATP, which was subsequently hydrolyzed to ADP, then the organelles separated from the microtubules. By looking for a protein that binds microtubules in the presence of AMPPNP and is released upon the addition of ATP, researchers were able to purify the motor protein, which they called *kinesin*.

Many kinesins have now been purified. Kinesin-1 isolated from squid giant axons is a dimer of two heavy chains, each associated with a light chain, with a total molecular weight of about 380,000 Da. The molecule contains a pair of globular N-terminal *head domains* connected by a short flexible *linker domain* to a long *central stalk*, and ends in a pair of small globular *tail domains*, which associate with the light chains (Figure 18-18). Each domain carries out a particular function: the head domain binds microtubules and ATP and is responsible for the motor activity of kinesin; the linker domain is critical for forward movement; the stalk domain is involved in dimerization through a coiled-coil interaction (see Figure 3-7a) of the two heavy chains; and the tail domain is responsible for binding to receptors on the membrane vesicles containing cargo.

FIGURE 18-18 Structure of kinesin-1. (a) Representation of kinesin-1 showing the two intertwined heavy chains, each with a motor domain in the head region. Each head is attached to the coiled-coil stalk by a flexible linker domain. Two light chains associate with the tail of the heavy chain. See R. D. Vale, 2003, *Cell* **112**:467. (b) X-ray structure of the kinesin heads with the microtubule-binding and nucleotide-binding sites (containing ADP) indicated, including the linkers and the beginning of the stalk region. See M. Thormahlen et al., 1998, *J. Struct. Biol.* **122**:30.

[Data from F. Kozielski et al., 1997, *Cell* **91**:985–994, PDB ID 3kin.]

Kinesin-1-dependent movement of vesicles can be tracked by in vitro motility assays similar to those used to study myosin-dependent movements (see Figure 17-23). In one type of assay, a vesicle or a bead coated with kinesin-1 was added to a glass slide along with a preparation of stabilized microtubules and observed in a microscope. In the presence of ATP, the beads were seen to move in one direction along a microtubule. Researchers found that beads coated with kinesin-1 always moved from the (−) to the (+) end of a microtubule (Figure 18-19). Thus kinesin-1 is a (+) end–directed microtubule motor protein, and additional evidence shows that it mediates anterograde transport of organelles along the axon.

FIGURE 18-19 Model of kinesin-1-catalyzed vesicle transport. Kinesin-1 molecules, attached to receptors on the vesicle surface, transport the vesicles from the (−) end to the (+) end of a stationary microtubule. ATP is required for movement. See R. D. Vale et al., 1985, *Cell* **40**:559; and T. Schroer et al., 1988, *J. Cell Biol.* **107**:1785.

The Kinesins Form a Large Protein Superfamily with Diverse Functions

Following the discovery of kinesin-1, a number of proteins with similar motor domains were identified by both genetic screens and molecular biology approaches. There are now 14 known classes of kinesins in animals, defined as sharing amino acid sequence homology with the motor domain of kinesin-1. Proteins of the kinesin superfamily are encoded by about 45 genes in the human genome. Although the functions of all these proteins have not yet been elucidated, some are involved in organelle, mRNA, and

chromosome transport; microtubule sliding; and microtubule depolymerization.

As with the different classes of myosin motors, in the kinesin families the conserved motor domain is fused to a variety of class-specific nonmotor domains (Figure 18-20). Whereas kinesin-1 has two identical heavy chains and two identical light chains, members of the kinesin-2 family (also involved in organelle transport) have two different heavy-chain motor domains and a third polypeptide that associates with the tail and binds cargo. Members of the bipolar kinesin-5 family have four heavy chains, forming bipolar motors that can cross-link antiparallel microtubules and, by walking toward the (+) end of each microtubule, slide them past each other. The kinesin-14 motor proteins are the only known class to move toward the (−) end of a microtubule; this class functions in mitosis. Members of the kinesin-13 family have two subunits, but with the conserved kinesin domain in the middle of the polypeptide. Kinesin-13 proteins do not have motor activity; instead, they are special ATP-hydrolyzing proteins that can enhance the depolymerization of microtubule ends (see Figure 18-15).

FIGURE 18-20 Structure and function of selected members of the kinesin superfamily. Examples of the structure and mode of action of some kinesin family members. Different kinesins have been given many different names; we use the unified nomenclature described in C. J. Lawrence et al., 2004, *J. Cell Biol.* **167**:19–22. See R. D. Vale, 2003, *Cell* **112**:467.

Kinesin-1 Is a Processive Motor

Optical trap and fluorescence-labeling techniques similar to those used to characterize myosin (see Figures 17-28 and 17-29) have been used to study how kinesin-1 moves down a microtubule and how ATP hydrolysis is converted into mechanical work. Such experiments demonstrate that kinesin-1 is a highly processive motor, meaning that it takes hundreds of steps down a microtubule without dissociating from it. During this process, the double-headed molecule moves along the same protofilament within the microtubule. The two heads work in a coordinated manner so that one is always attached to the microtubule.

The kinesin-1 heads bind a microtubule very tightly when they are in either an ATP-bound or nucleotide-free state, but binding is weak when ADP occupies the nucleotide-binding sites. It is these properties that account for the ability of kinesin-1 to move cargo in a processive manner. The ATP cycle of kinesin-1 movement is most easily understood if we begin just after the motor has taken a step (Figure 18-21a). At this point, the motor has a nucleotide-free leading head, which is strongly bound to a tubulin dimer in a protofilament, and an ADP-bound trailing head, which is weakly associated with the protofilament (Figure 18-21a, state **1**). ATP then binds to the leading head (Figure 18-21a, state **2**), and this binding induces a conformational change so that the neck linker of this leading head is no longer free and pointing backward, but now swings forward and *docks* into the head. This swinging motion causes the linker domain to rotate forward, which throws the

trailing head — like throwing a ballet dancer — into position to become the leading head (Figure 18-21a, state **3**). The new leading head finds the next binding site 16 nm ahead on the microtubule (Figure 18-21a, state **4** and Figure 18-21b). This step, which moves the cargo 8 nm, is the power stroke. The interaction of the leading head with the microtubule induces coordinated events between the two heads. First, it induces the leading head to release ADP to generate the nucleotide-free state and therefore bind the microtubule tightly. Second, it induces the trailing head to hydrolyze ATP to ADP and P_i, and upon releasing P_i transition into the weakly bound state (Figure 18-21a, step **5**). ATP can now bind to the leading head to repeat the cycle and allow the protein to take another step down the microtubule. During this cycle, one head is always in the ATP or nucleotide-free state, both of which result in tight binding to the microtubule, so kinesin very rarely dissociates as it walks along a microtubule, thereby accounting for its ability to take thousands of steps along a microtubule without disassociating from it.

FIGURE 18-21 Kinesin-1 uses ATP to walk down a microtubule. (a) In this diagram, the two kinesin heads are shown with differently colored linker domains (yellow and red) to distinguish them. The cycle is shown starting after kinesin has taken a step, with the leading head in the nucleotide-free state and tightly bound to the microtubule, while the trailing head is weakly bound to the microtubule because it has ADP bound (state 1). The leading head then binds ATP (state 2), which induces a conformational change that causes the yellow linker region to swing forward and dock into its associated head domain, thereby thrusting the trailing head forward (state 3). The new leading head now finds a binding site 16 nm down the microtubule, to which it binds weakly (state 4). The leading head releases ADP and binds tightly to the microtubule, and coordinately the trailing head hydrolyzes ATP to ADP and P_i, and releases P_i. This converts the trailing head into a weak binding state, and also releases the docked linker region (state 5). The cycle now repeats

itself for another step. See R. D. Vale and R. A. Milligan, 2000, *Science* **288**:88. (b) Structural model of two kinesin heads (purple) bound to a protofilament in a microtubule. The trailing head, at left, has bound ATP and has thrust the other head into the leading position. Notice how the linker region (yellow) is docked into the trailing head, whereas the linker region (red) of the leading head is still free.

[Part (b) Data from E. P. Sablin and R. J. Fletterick, 2004, *J. Biol. Chem.* **279**:15707 and custom PDB files based on 3kin, 1mkj, and 1jff.]

As a transporter of organelles, kinesin-1 must bind and transport the correct cargo. It does this through receptor proteins on the appropriate organelle that bind to the tail domain of the motor protein. Since kinesin-1 is an ATPase, it is important that this activity be inactivated to conserve energy when it is not needed and also after releasing the organelle following transport. To accomplish this, kinesin-1 can fold into an inactive state in which the tail domain interacts with the motor head domain to inhibit both its ATPase activity and microtubule binding (Figure 18-22). When the tail binds the cargo-associated receptor protein, the motor unfolds and is activated (step **1**). When the cargo-activated motor complex encounters a microtubule, it transports the organelle (step **2**). Upon organelle delivery, kinesin-1 is released from the cargo and is inactivated by refolding into the head-to-tail inhibited state.

FIGURE 18-22 Kinesin-1 is regulated by a head-to-tail interaction. In its inhibited form, the head of kinesin-1 folds back and interacts with the tail. This interaction inhibits the ATPase activity of kinesin-1. When the motor encounters an appropriate receptor, here shown on a vesicle, it unfolds (step 1) and is now able to transport the cargo toward the (+) end of a microtubule (step 2). It is not yet clear how the motor dissociates from the cargo when they arrive at the destination, but it involves cargo release and folding back into the inhibited state.

When the x-ray crystallographic structure of the kinesin head was determined, it revealed a major surprise — the catalytic core has the same overall structure as myosin's (Figure 18-23)! This is the case despite the fact that there is no amino acid sequence conservation between the two proteins, arguing strongly that convergent evolution has twice generated a fold that can use the hydrolysis of ATP to generate work. Moreover, the same type of three-

dimensional structure is seen in small GTP-binding proteins, such as Ras, that undergo a conformational change upon GTP hydrolysis.

FIGURE 18-23 Convergent structural evolution of the ATP-binding cores of myosin and kinesin heads. The common catalytic cores of myosin and kinesin are shown in yellow, the nucleotide in red, and the lever arm (for myosin-II) and linker domain (for kinesin-1) in light purple. See R. D. Vale and R. A. Milligan, 2000, *Science* **288**:88.

Dynein Motors Transport Organelles Toward the (−) Ends of Microtubules

Cells use a different motor protein to transport organelles in a retrograde direction toward the (−) ends of microtubules.

Cytoplasmic dynein is very large; the human version is a 1.4-MDa complex consisting of two heavy, two intermediate, two light intermediate, and six light chains. In addition to its role in retrograde transport of organelles toward the (−) ends of microtubules in axons, dynein has many other functions, which we consider later in the chapter. Compared with the myosins and the kinesins, the family of dynein-related proteins is not very diverse. For example, only one gene encodes the human dynein heavy chain.

Like kinesin-1, cytoplasmic dynein is a two-headed molecule, built around two heavy chains. A single dynein heavy chain consists of a number of distinct domains (Figure 18-24a). The first is the *stem*, to which the other dynein subunits bind, and which associates with cargo through another protein complex, dynactin, that we discuss shortly. The next part of the heavy chain is a *linker* that plays a critical role during ATP-dependent motor activity. A large part of the heavy chain makes up the *head* containing the *AAA ATPase* domain, consisting of six repeats that assemble into a flowerlike structure (Figure 18-24b), within which lies the ATPase activity. Embedded between the fourth and fifth AAA repeats is the *stalk*, which protrudes from the structure and contains the microtubule-binding region.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 18-24 The domain structure of cytoplasmic dynein. (a) The dynein heavy chain, consisting of over 4000 amino acid residues, has several distinct domains. Following the stem and linker domains are six AAA repeats (peach, numbered 1–6), with the stalk and its microtubule-binding domain between repeats 4 and 5. (b) The six AAA repeats of each heavy chain assume a structure like petals on a flower. Emerging from this structure is a coiled-coil stalk domain with a microtubule-binding site at the end. A number of additional subunits associate with the stem region and can link dynein to cargo through dynactin (see Figure 18-26). See R. D. Vale, 2003, *Cell* **112**:467.

Electron microscopy, combined with x-ray images of the structure of a dynein heavy chain, provides a glimpse of how dynein might work. The first AAA repeat is probably the only one involved in converting the hydrolysis of ATP into mechanical work. In the absence of a bound nucleotide, dynein binds to microtubules. Note that the linker is straight, lies across the AAA domain, and associates with the first and fifth AAA repeats. Upon ATP binding, dynein dissociates from the microtubule and the linker becomes bent. The linker now crosses between the second and third AAA repeats ("pre-stroke"; Figure 18-25a and b, *left panels*). Interaction with a microtubule, ATP hydrolysis, and release of P_i cause the linker to straighten. This straightening is the power stroke that moves the cargo toward the (−) end of the microtubule ("post-stroke"; Figure 18-25a and b, *right panels*). The ADP is released, and the motor head remains bound to the microtubule. When ATP binds, the head is released, and the cycle repeats for another step.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 18-25 The power stroke of dynein. (a) Multiple images of purified single-headed dynein molecules in their pre-stroke and post-stroke states were recorded in an electron microscope and then averaged. The image at the left shows dynein in the pre-stroke state, and the image at the right shows it in the

post-stroke state. (b) A comparison of the microscopic images combined with structural data shows that the force-generation mechanism involves a change in the position of the linker, which causes a movement of the microtubule-binding stalk. For clarity, only one of the two dynein heads is shown. See G. Bhabha et al., 2014, *Cell* **159**:857.

[Part (a) Reprinted by permission from Nature Publishing Group, from S. A. Burgess et al., 2003, "Dynein Structure and Power Stroke," *Nature* **421**(6924):715–718; permission conveyed through Copyright Clearance Center, Inc.]

Unlike kinesin-1, cytoplasmic dynein cannot mediate cargo transport by itself. Rather, dynein-related transport requires a large protein complex, called *dynactin*, that links dynein to its cargo (Figure 18-26). Dynactin consists of 11 different types of subunits, functionally organized into two domains. One domain is built around one actin subunit and eight copies of the actin-related protein Arp1 assembled into a short filament. The end corresponding to the (+) end of this filament is capped by CapZ, the same capping protein that binds the (+) end of an actin filament (see Figure 17-12). A number of other subunits are associated with the (−) end. This Arp1-containing domain is responsible for binding cargo. The second domain of dynactin consists of a long protein called $p150^{Glued}$, which contains the dynein-binding site and has a microtubule-binding site at one end. Holding the two dynactin domains together is a protein called *dynamitin* — so named because when it is overexpressed, it dissociates (or "blows apart") the two domains, making a nonfunctional complex. This feature has been very useful experimentally because it has allowed researchers to

identify processes that are dependent on the interaction of dynein and dynactin, which are disrupted in cells overexpressing dynamitin.

FIGURE 18-26 The dynactin complex functions with dynein to transport cargo. (a) One domain of the dynactin complex is built around a short filament made up of eight subunits of the actin-related protein Arp1 and one actin subunit, capped by CapZ. Another domain consists of the protein $p150^{Glued}$, which has a microtubule-binding site on its distal end and is also involved in attaching cytoplasmic dynein to the complex. Dynamitin holds the two parts of the dynactin complex together. (b) Diagram of how dynactin and dynein interact with each other and with an activating adaptor and a microtubule. See L. Urnavicius et al., 2015, *Science* **347**:1441.

Recent work has shown that the dynein-dynactin complex exists in an inactive form until it encounters activating adaptors, which both activate the motor and link it to cargo. There are many activating adaptors; each functions with a specific cargo. All of the adaptors are dimeric proteins with a distinct cargo-binding site and a long coiled-coil region that interacts with dynactin (Figure 18-26b). In some circumstances, dynein must be transported in an inactive form to a specific location, where it is then activated. For example, it has been found that the dynactin $p150^{Glued}$ subunit binds +TIP protein EB1, allowing dynein to become associated with the growing (+) end of a microtubule. Why would dynein associate with the microtubule (+) end if it is a (−) end–directed motor? Recent work suggests that when dynein is associated with the (+) end of a microtubule via the dynactin-EB1 interaction, it is held in an inactive conformation. When the growing microtubule reaches the cell cortex, the inactive dynein and dynactin encounter an activator that is localized there. The dynein now becomes active, associating with the cortex and pulling on the microtubule that delivered it there! This mechanism has been shown to help orient the mitotic spindle in yeast, and it probably applies to other situations as well.

In addition to dynactin, other proteins function with dynein. One group of proteins, which includes LIS1 and NudE, is involved in regulating the activity of dynein during brain development. NudE links the dynein intermediate and light chains to LIS1 (Figure 18-27a). LIS1 then interacts with the ATPase domain of dynein to

lengthen the duration of the power stroke, making the motor more processive under conditions of high load. Defects in LIS1 cause the fatal disease Miller-Dieker lissencephaly (from which the protein got its name); *lissencephaly* means "smooth brain," as cortical folds and grooves are lacking in the brains of patients with this condition (Figure 18-27b). Mutations in LIS1 result in defects in both neuronal mitoses and neuronal migration in early development, resulting in the smooth-brain phenotype and defects in mental development as well as many other abnormalities. ■

Kinesins and Dyneins Cooperate in the Transport of Organelles Throughout the Cell

Dyneins and kinesins play important roles in the microtubule-dependent organization of organelles in cells (Figure 18-28). Recall that the orientation of microtubules is fixed by the microtubule organizing center, or MTOC. So the direction of transport — toward or away from the cell center — depends on the motor proteins. For example, the Golgi complex collects in the vicinity of the centrosome, where the (−) ends of microtubules lie, and is driven there by dynein-dynactin. When secretory cargo emerges from the endoplasmic reticulum, it is transported to the Golgi by dynein-dynactin. The endoplasmic reticulum is spread throughout the cytoplasm and is transported there by kinesin-1, which moves toward the (+) ends of microtubules, located toward the cell's periphery. Some organelles of the endocytic pathway, including late endosomes and lysosomes, are associated with dynein-dynactin complexes. Kinesins transport mitochondria as well as

nonmembranous cargo such as mRNAs encoding proteins that need to be localized to specific regions of the cell during development.

FIGURE 18-28 Organelle transport by microtubule motors. Cytoplasmic dyneins (red) mediate retrograde transport of organelles toward the (−) ends of microtubules (cell center); kinesins (purple) mediate anterograde transport toward the (+) ends (cell periphery). Most organelles have one or more microtubule-based motors associated with them. It should be noted that the association of motors with organelles varies by cell type, so some of these associations may not exist in all cells, whereas others not shown here also exist.

We have seen how kinesin-1 transports organelles in an anterograde direction down axons. What happens to the motor when it gets to

the end of the axon? It is carried back in a retrograde direction on organelles transported by cytoplasmic dynein. Thus kinesin-1 and dynein can associate with the same organelle, and a mechanism must exist that turns one motor off while activating the other, although these mechanisms are not yet understood fully.

Much of what we know about the regulation of microtubule-based organelle transport comes from studies using fish (e.g., angelfish) or frog melanophores. Melanophores are cells of the vertebrate skin that contain hundreds of dark, melanin-filled pigment granules called *melanosomes*. Melanophores either have their melanosomes dispersed, in which case they make the skin darker, or aggregated at the cell center, which makes the skin paler (Figure 18-29). These changes in skin color, mediated by neurotransmitters in the fish and regulated by hormones in the frog, serve to camouflage the fish and enhance social interactions in the frog. The movement of the melanosomes is mediated by changes in intracellular cAMP and is dependent on microtubules. Studies investigating which motors are involved have shown that melanosome dispersion requires kinesin-2, whereas melanosome aggregation requires cytoplasmic dynein-dynactin. The first hints of how these activities might be coordinated came from the finding that overexpression of dynamitin inhibited melanosome transport in both directions. This surprising result was explained when it was found that dynactin can bind not only to cytoplasmic dynein but also to kinesin-2 — and may coordinate the activity of the two motors.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 18-29 Movement of pigment granules in frog melanophores. (a) Diagram of the microtubule-based reorganization of melanosomes according to the level of cAMP. Melanosomes are aggregated by cytoplasmic dynein and dispersed by kinesin-2. (b) Melanosomes (red) in the dispersed state as seen by immunofluorescence microscopy. Microtubules are labeled green, and the DNA in the nucleus is labeled blue.

The association of dynein and kinesin-2 with the same organelle is not limited to melanosomes. It has been suggested that these motors may cooperate to appropriately localize late endosomes, lysosomes, and mitochondria in some cells. Thus the association of organelles with a number of distinct motors is not the exception but an emerging theme.

Tubulin Modifications Distinguish Different Classes of Microtubules and Their Accessibility to Motors

The stability and functions of different classes of microtubules are influenced by post-translational modifications to tubulin. Although multiple types of modifications have been detected, we restrict our discussion here to those that are the best understood — lysine acetylation, detyrosylation, polyglutamylation, and polyglycylation (Figure 18-30a).

EXPERIMENTAL FIGURE 18-30 Post-translational modifications of tubulin affect the stability and function of microtubules. (a) Structure of α- and β-tubulin, showing the sites of lysine acetylation on the inner surface of the microtubule and polyglutamylation, polyglycylation, and detyrosylation on the outer surface. Note that polyglutamylation and polyglycylation are likely mutually exclusive, so they would not normally occur at the same time. See J. W. Hamond, D. Cai, and K. J. Verhey, 2008, *Curr. Opin. Cell Biol.* **20**:71–76. (b) Detyrosylated microtubules are preferentially oriented toward the leading edge of a moving cell. A cell migrating toward the right is stained for total microtubules (red) and detyrosylated microtubules (green). The resulting merged image shows the detyrosylated microtubules enriched toward the front of the cell in yellow, which is a combination of red and green.

[Part (a) data from E. Nogales, S. G. Wolf, and K. H. Downing, 1998, *Nature* **391**:199–203, PDB ID 1tub.]

Two of these modifications are found only on α-tubulin. The first is *acetylation* of the ε-amino group of a specific lysine residue of α-tubulin that lies on the inside of the microtubule. Microtubules with this acetylated lysine are stabilized against breakage and are found on microtubule structures such as centrioles, basal bodies, and primary cilia (primary cilia are discussed in Section 18.5). Indeed,

cells unable to acetylate tubulin have defective primary cilia, whereas cells in which the acetylation cannot be removed have unusually stable primary cilia. The second modification of α-tubulin involves its C-terminal tyrosine. This tyrosine can be removed by a carboxypeptidase that functions only when bound to the surface of a microtubule, where it sequentially removes the C-terminal tyrosines from α-tubulin subunits. Such *detyrosylated* microtubules are more stable, because they are more resistant to depolymerization by kinesin-13 and related proteins. Moreover, in migrating cells, these more stable microtubules are generally oriented toward the front of the cell (Figure 18-30b). When a detyrosylated microtubule depolymerizes, the α-tubulin subunit of the αβ-dimer has the C-terminal tyrosine added back by a tyrosine ligase that acts only on soluble tubulin, and the αβ-tubulin dimer can now be used during elongation of another growing microtubule.

The C-terminal regions of both α- and β-tubulin are rich in glutamic acid residues, and specific enzymes can modify these residues. These modifications occur only after assembly of the microtubule. The tubulin tails can be modified by *polyglutamylation*, in which a chain of glutamic acid residues is linked to a specific glutamate residue, or by *polyglycylation*, in which a chain of glycine residues is added to a different glutamate residue. These two modifications are likely mutually exclusive, so that a tubulin subunit modified by polyglycylation is protected from polyglutamylation, and vice versa.

Like detyrosylation, both polyglycylation and polyglutamylation can enhance microtubule stability.

These post-translational modifications of tubulin not only affect microtubule stability but can also influence the ability of molecular motors to interact with microtubules. Kinesin-1 associates preferentially with detyrosylated and acetylated microtubules, so these modifications may be important in recruiting this motor for axonal transport in neurons. As is illustrated in Figure 18-5e, neurons have different microtubule organizations in their dendrites and their axons. The microtubules in the axon are stabilized by acetylation and detyrosylation, which allows kinesin-1 to associate preferentially with them for axonal transport. Polyglutamylation has a key role in the beating of cilia and flagella, which we discuss in the next section.

Research elucidating the effects of post-translational modifications of tubulin on microtubule function and microtubule-based motors is all quite recent. We can expect future studies to reveal so-called codes used by the cell that distinguish among different classes of microtubules and impart specific functions to the different types of microtubules.

KEY CONCEPTS OF SECTION 18.4

Kinesins and Dyneins: Microtubule-Based Motor Proteins

- Kinesin-1 is a microtubule $(+)$ end–directed ATP-dependent motor protein that transports membrane-bounded organelles (see Figure 18-19).
- Kinesin-1 consists of two heavy chains, each with an N-terminal motor domain, and two light chains that associate with cargo (see Figure 18-18).
- The kinesin superfamily includes motors that function in interphase and mitotic cells, transporting organelles and sliding antiparallel microtubules past each other. The superfamily includes one class, kinesin-13, that is not motile but instead destabilizes microtubule ends (see Figure 18-20).
- Kinesin-1 is a highly processive motor because it coordinates ATP hydrolysis between its two heads so that one head is always firmly bound to a microtubule (see Figure 18-21).
- Kinesin-1 can exist in an inactive folded conformation or in a cargo-associated extended conformation (see Figure 18-22).
- Cytoplasmic dynein is a microtubule $(-)$ end–directed ATP-dependent motor that associates with the dynactin complex and activating adapters to transport cargo (see Figures 18-24 and 18-26).
- Kinesins and dyneins associate with many different organelles to organize their locations in cells (see Figure 18-28).
- Post-translational modifications of tubulin can affect the stability of microtubules and regulate their ability to interact with microtubule-based motors.

18.5 Cilia and Flagella: Microtubule-Based Surface Structures

Cilia and **flagella** are microtubule-based and membrane-enveloped extensions of the plasma membrane that project from many protozoan and most animal cells. Abundant motile cilia are found on the surfaces of specific epithelia, such as those that line the trachea (see Figure 4-35), where they beat in an orchestrated, wavelike fashion to move fluids. Animal-cell flagella, which are longer than cilia but have a similar structure, can propel a cell, such as a sperm, through liquid. Cilia and flagella contain many different microtubule-based motors: axonemal dyneins are responsible for the beating of flagella and cilia, whereas kinesin-2 and cytoplasmic dynein are responsible for flagellum and cilium assembly and turnover.

Eukaryotic Cilia and Flagella Contain Long Doublet Microtubules Bridged by Dynein Motors

Cilia and flagella range in length from a few micrometers to more than 2 mm for some insect sperm flagella. They possess a central bundle of microtubules, called the **axoneme**, which consists of a

9 + 2 arrangement of nine doublet microtubules surrounding a central pair of singlet microtubules (Figure 18-31a, c). Each of the nine outer doublets consists of an A microtubule with 13 protofilaments and a B microtubule with 10 protofilaments (see Figure 18-4). All the microtubules in cilia and flagella have the same polarity: the (+) ends are located at the distal tip. At its point of attachment in the cell, the axoneme connects with the *basal body*, a complicated structure containing nine triplet microtubules (Figure 18-31a, b).

FIGURE 18-31 Structural organization of cilia and flagella. (a) Cilia and flagella are assembled from a basal body, a structure built around nine linked triplet microtubules. Continuous with the A and B microtubules of the basal body are the A and B tubules of the axoneme — the membrane-enveloped core of the cilium or flagellum. Between the basal body and axoneme is the transitional zone. (b) Electron micrograph of a longitudinal section (*left*) and indicated transverse sections (*right*) through a basal body and part of the axoneme of a cilium showing the intricate structure of a basal body, the transitional zone, and

axoneme. (c) Diagram of a transverse section of a cilium, to show the identity of the structures. See S. K. Dutcher, 2001, *Curr. Opin. Cell Biol.* **13**:49–54.

[Part (b) S. Vaughan, K. Gull, 2015, "Basal Body Structure and Cell Cycle-Dependent Biogenesis in *Trypanosoma brucei*," *Cilia* **5**:5, https://doi.org/10.1186/s13630-016-0023-7.]

The axoneme is held together by three sets of protein cross-links (Figure 18-31c). The two central singlet microtubules are connected to each other by periodic bridges, like rungs on a ladder. A second set of linkers, composed of the protein *nexin*, joins adjacent outer doublet microtubules to each other. *Radial spokes* project from each A tubule of the outer doublets toward the central pair.

The major motor protein present in cilia and flagella is *axonemal dynein*, a large, multisubunit protein related to cytoplasmic dynein. Two rows of axonemal dynein motors are attached periodically down the length of each A tubule of the outer doublet microtubules; these motors are called the *inner-arm* and *outer-arm* dyneins (see Figure 18-31c). It is the interaction of these dynein motors with the B tubule in the adjacent doublet that brings about ciliary and flagellar bending.

Ciliary and Flagellar Beating Are Produced by Controlled Sliding of Outer Doublet Microtubules

Activation of the axonemal dynein motors causes cilia and flagella to bend. A close examination of this movement using live cell imaging reveals that a bend starts at the base of a cilium or flagellum and then propagates along the structure (Figure 18-32). A clue to how this occurs came from studies of isolated axonemes. In these classic experiments, axonemes were gently treated with a protease that cleaves only the nexin linkers. When ATP was added to the treated axonemes, the doublet microtubules slid past one another as dynein, attached to the A tubule of one doublet, walked down the B tubule of the adjacent doublet (Figure 18-33b, c). In an axoneme with intact nexin linkers, the action of dynein induces flagellar bending because the microtubule doublets are connected to one another (Figure 18-33a).

EXPERIMENTAL FIGURE 18-32 Live cell imaging shows flagellar movements that propel sperm and *Chlamydomonas* forward. In both cases, the cells are moving to the left. (a) In the typical sperm flagellum, successive waves of bending originate at the base and are propagated out toward the tip; these waves push against the surrounding fluid and propel the cell forward. In this sequence, a bend at the base of the flagellum in the first (*top*) frame has moved distally halfway along the flagellum by the last frame. A pair of gold beads attached to the flagellum are seen to slide apart as the bend moves through their region. (b) Beating of the two flagella on *Chlamydomonas* occurs in two stages, called the *effective stroke* (top three frames) and the *recovery stroke* (remaining frames). The effective stroke pulls the organism through the water. During the recovery stroke, a different wave of bending moves outward from the bases of the flagella, pushing the flagella along the surface of the cell until they reach the position to initiate another effective stroke. Beating commonly occurs 5–10 times per second.

[Part (a) C. J. Brokaw, 1991, *J. Cell Biol.* **114**(6):1201–1215; https://doi.org/10.1083/jcb.114.6.1201.]

FIGURE 18-33 Ciliary and flagellar bending is mediated by axonemal dynein. (a) Axonemal dynein attached to an A tubule of an outer doublet pulls on the B tubule of the adjacent doublet trying to move toward the (−) end. Because the adjacent tubules are tethered by nexin, the force generated by dynein bends the cilium or flagellum. (b) Experimental evidence for the model in (a). When the nexin linkers are cleaved with a protease and ATP added to induce dynein activity, the microtubule doublets slide past one another. (c) Electron micrograph of two doublet microtubules in a protease-treated axoneme incubated with ATP. In the absence of cross-linking proteins, doublet microtubules slide excessively. The dynein arms can be seen projecting from A tubules and interacting with B tubules of the left microtubule doublet.

We don't yet fully understand how specific subsets of dynein are activated and how a wave of activation is propagated down the axoneme, but post-translational modifications of tubulin may play a role. Recall from Section 18.4 that post-translational modifications of tubulin subunits can affect the interactions between microtubules and motor proteins. The B tubules of the outer axoneme doublets are often polyglutamylated, and this modification strongly affects the interaction of the inner-arm dynein with the B tubule. Because inner-arm dynein motors mainly affect the waveform of the ciliary beat, it is this aspect of ciliary function that is compromised in mutants unable to undergo polyglutamylation.

Intraflagellar Transport Moves Material Up and Down Cilia and Flagella

Although axonemal dynein is involved in bending cilia and flagella, another type of motility has been observed in these structures. Careful examination of flagella on the biflagellate green alga *Chlamydomonas reinhardtii* revealed cytoplasmic particles moving at about 2.5 μm/s toward the tip of a flagellum (anterograde movement) and other particles moving at about 4 μm/s from the tip to the base (retrograde movement). This movement, known as *intraflagellar transport (IFT)*, occurs in both cilia and flagella. Light and electron microscopy revealed that the particles move along a path that runs parallel to the outer doublet microtubules and the plasma membrane (Figure 18-34). Analysis of algal mutants demonstrated that the anterograde movement is powered by kinesin-2 and the retrograde movement by cytoplasmic dynein. Remarkably, anterograde-moving particles can move past retrograde-moving particles without interference. This is because the particles move along distinct microtubules of the outer doublets: the anterogade particles powered by kinesin-2 move along the B-tubule and the retrograde particles powered by dynein move along the A-tubule.

FIGURE 18-34 Intraflagellar transport. (a) Particles are transported between the plasma membrane and the outer doublet microtubules. Transport of the particles to the tip is dependent on kinesin-2, whereas transport toward the base is mediated by cytoplasmic dynein. (b) This thin-section electron micrograph shows IFT particles in a section of a *Chlamydomonas* flagellum.

[Part (b) Reprinted by permission from Nature Publishing Group, from J. L. Rosenbaum and G. B. Witman, 2002, "Intraflagellar Transport," *Nat. Rev. Mol. Cell Biol.* **3**:813–825; permission conveyed through Copyright Clearance Center, Inc.]

The anterograde and retrograde IFT particles transported in *Chlamydomonas* flagella have been isolated and their composition determined. They consist of two distinct protein complexes, called *IFT complex A* and *IFT complex B*. By analyzing the phenotypes of cells having mutations affecting these complexes, it has been found that complex B is necessary for anterograde IFT, whereas complex A is important for retrograde IFT. Despite this segregation of function,

both complexes are transported in both directions. All the components of IFT particles have homologs in organisms containing cilia, such as nematodes, fruit flies, mice, and humans, but these particles are absent from the genomes of yeasts and plants that lack cilia, suggesting that they are specific to IFT.

What is the function of IFT? Because all the microtubules in a flagellum have their growing (+) ends at the tip, that is the site where new tubulin subunits and flagellar structural proteins are added. Moreover, even in cells with flagella of uniform length, the microtubules are turning over, with assembly and disassembly occurring at the flagellar tip. In cells defective for kinesin-2, flagella shrink, suggesting that IFT transports new material to the tip for growth. Since IFT is a continually occurring process, what happens to the kinesin-2 molecules when they get to the tip, and where do the dynein motors come from to transport the particles retrogradely? Remarkably and similar to the situation in axonal transport, dynein is carried to the tip as cargo on the anterograde-moving particles, powered by kinesin-2, and then kinesin-2 becomes cargo as the particles are transported back to the base by dynein.

Primary Cilia Are Sensory Organelles on Interphase Cells

Many vertebrate cells bear a solitary nonmotile cilium known as the **primary cilium**. The primary cilium is a stable structure that is resistant to drugs such as colchicine that disassemble most microtubules. After colchicine treatment, the only remaining microtubules are found in the centrioles and the primary cilium (see Figure 18-12). Moreover, the tubulin in the primary cilium is highly acetylated, so using antibodies that specifically recognize acetylated α-tubulin readily identifies the single primary cilium on each interphase cell (Figure 18-35a).

FIGURE 18-35 Many interphase cells contain a nonmotile primary cilium. (a) Fluorescence micrograph of mouse epithelial cells stained with antibodies to acetylated α-tubulin (green), which decorate the primary cilia; to pericentrin (magenta), which decorate the centrosome; and to ZO-1 (red), which label the tight junctions that encircle each cell. (b) The centrosome

contains two centrioles in the G1 or G0 stage of the cell cycle, with one of the centrioles functioning as a basal body for the primary cilium. During S phase, the centrosome duplicates in preparation for mitosis. As cells enter mitosis, the primary cilium is disassembled and the duplicated centrosomes form the spindle poles. (c) A diagram depicting a section through a nonmotile primary cilium, showing the lack of the central pair of microtubules and dynein arms typical of motile cilia and flagella. (d) Scanning electron micrographs of epithelial cells of a kidney collecting tubule from a wild-type mouse (*left*) and a mutant mouse defective in a component of the IFT particles. Arrows point to the primary cilia, which are short stubs in the mutant mouse.

Engel et al., 2011, "A Cell-Based Screen for Inhibitors of Flagella-Driven Motility in *Chlamydomonas* Reveals a Novel Modulator of Ciliary Length and Retrograde Actin Flow," *Cytoskeleton* **68**(3):188–203; permission conveyed through Copyright Clearance Center, Inc. Part (d) G. J. Pazour et al., 2000, *J. Cell Biol.* **151**(3):709–718; https://doi.org/10.1083/jcb.151.3.709.]

Terminally differentiated cells and dividing cells not in mitosis contain a primary cilium. In the latter case, the presence of the primary cilium is tied to the duplication cycle of the centrioles (discussed in Section 8.6), with the older, mother centriole functioning as the basal body for the assembly of the primary cilium (Figure 18-35b). Thus the centrosome, consisting of the two centrioles and pericentriolar material (see Figure 18-6), serves both as the basal body for the primary cilium and as the MTOC for the organization of the cytoplasmic array of microtubules.

The primary cilium is nonmotile because it lacks the central pair of microtubules and the dynein arms that are found in other cilia and in flagella (Figure 18-35c), but it does retain the IFT transport system. Work in the past several years has shown that the primary

cilium is a sensory organelle, acting as the cell's antenna by detecting extracellular signals. For example, our sense of smell is due to odorants binding to receptors located in the primary cilia of olfactory sensory neurons in the nose (see Chapter 23). In another example, the rod and cone cells of the eye have a primary cilium with a greatly expanded tip to accommodate the proteins involved in photoreception. The retinal protein opsin moves through the primary cilium at about 2000 molecules per minute, transported by kinesin-2 as part of the IFT system. Defects in this transport cause retinal degeneration. In vertebrates, the primary cilium is the site of action of the Hedgehog signaling pathway, as described in Chapter 16.

The primary cilium has a diffusion barrier at its base so that only the appropriate proteins can enter it: globular proteins of 10 kDa have ready access, but proteins above 40 kDa are excluded. Remarkably, transport through this barrier has similarities to transport into the nucleus through nuclear pores, and indeed, these two forms of transport have some components in common. Recall that import though nuclear pores requires a gradient of the Ran GTPase and involves binding of cargo proteins to importins (see Section 13.6). Transport of at least some proteins, such as kinesin-2, across the base and into a primary cilium requires both a gradient of the Ran GTPase and importins.

Defects in Primary Cilia Underlie Many Diseases

For many years, the existence and function of the primary cilium was ignored. However, this situation has changed dramatically over the last decade as we have come to appreciate that defects in intraflagellar transport result in the loss of primary cilia in mice (Figure 18-35d), and many diseases have now been traced to defects in primary cilia and IFT. One of the first clues came from the discovery that loss of a mammalian homolog of a *Chlamydomonas* IFT protein results in defects in the primary cilia and causes autosomal dominant polycystic kidney disease (ADPKD). It is hypothesized that the primary cilia on the epithelial cells of the kidney collecting tubule act as mechanochemical sensors to measure the rate of fluid flow by the degree to which they are bent.

In another example, patients with Bardet-Biedl syndrome have retinal degeneration, polydactyly (from the Greek for "many fingers"), and obesity. The syndrome can be caused by mutations in any one of 14 genes and has been traced to defects in the function of primary cilia. Many of these genes encode subunits of the BBsome, an octameric complex that forms a coat with structural elements in common with COPI, COPII, and clathrin (described in Chapter 14) and that traffics membrane proteins to cilia. While defects in many of the BBsome's components do not affect the structure of the primary cilium itself, they result in a lack of specific membrane

receptors that would normally be delivered to primary cilia through the interaction of the BBsome with the IFT apparatus. For example, the polydactyly seen in patients with Bardet-Biedl syndrome is due to a loss of localized Hedgehog signaling (see Chapter 16) in the primary cilium that is necessary for patterning during embryogenesis. ■

KEY CONCEPTS OF SECTION 18.5

Cilia and Flagella: Microtubule-Based Surface Structures

- Cilia and flagella are microtubule-based cell-surface structures with a characteristic central pair of singlet microtubules and nine sets of outer doublet microtubules (see Figure 18-31).
- All cilia and flagella grow from basal bodies, structures with nine sets of outer triplet microtubules that are closely related to centrioles.
- Axonemal dyneins attached to the A tubule on one doublet microtubule interact with the B tubule of another to bend cilia and flagella.
- Cilia and flagella have a mechanism, intraflagellar transport (IFT), in which material is transported to the tip by kinesin-2 and from the tip back to the base by cytoplasmic dynein. IFT regulates the function and length of cilia and flagella.
- Many cells have on their surface a single nonmotile primary cilium, which lacks the normal central pair of microtubules and the dynein arms of motile cilia. The primary cilium functions as a sensory organelle, with receptors for extracellular signals localized to its plasma membrane.
- Due to its sensory function, many diseases result from defects in receptor localization or in the structure of the primary cilium itself.

18.6 Mitosis

Of all the processes that permit the existence and perpetuation of life, perhaps the most critical is the ability of cells to accurately duplicate and then faithfully segregate their chromosomes at each cell division. During the **cell cycle**, a highly regulated process discussed in Chapter 19, cells precisely duplicate their chromosomes once during a period known as *S phase* (for DNA synthesis phase). After duplication, the two copies of each duplicated chromosome are held together by proteins called *cohesins*. The cells then pass through a period called G_2 (for gap 2) before entering **mitosis**, the process by which the duplicated chromosomes are segregated to the daughter cells.

Mitosis has to be precise — loss or gain of a chromosome can be lethal to the cell or cause severe complications for the cell. It is estimated that a yeast cell only mis-segregates 1 of its 16 chromosomes every 100,000 cell divisions, which makes mitosis one of the most accurate processes in biology. To achieve this level of accuracy, the process is highly regulated so that it proceeds in an orderly series of steps that are free of errors. In addition, error detection mechanisms proofread the steps. When errors are detected, the process pauses so they can be corrected. The timing and mechanisms that ensure the fidelity of mitosis are regulated by the cell cycle circuitry that we discuss in detail in Chapter 19. Here

we limit our discussion of this circuitry as it applies to microtubules and the mechanics of mitosis.

In outline, the cell has to first organize the assembly of a machine (the spindle) to segregate the chromosomes, then attach the duplicated chromosomes to the spindle so that during segregation one copy of each chromosome moves toward each daughter cell, and finally the cell divides in two so that each daughter cell inherits a complete set of chromosomes.

Centrosomes Duplicate Early in the Cell Cycle in Preparation for Mitosis

In preparing to separate the chromosomes during mitosis, cells duplicate their MTOCs — their centrosomes — in a manner that is coordinated with the duplication of their chromosomes in S phase (Figure 18-36). As we discuss in Chapter 19, the cell cycle is largely driven by the association of cell-cycle-specific cyclins with cyclin-dependent kinases (CDKs). Two kinases — G_1/S phase CDK and Plk4 — promote centrosome duplication. The duplicated centrosomes separate as the cell enters mitosis in a process known as *centrosome disjunction* and then move to opposite sides of the nucleus to become the two poles that will establish the mitotic spindle. The number of centrosomes in animal cells is carefully controlled to ensure the assembly of an appropriate spindle. In fact, many tumor

cells have more than two centrosomes, which contributes to genetic instability resulting from mis-segregation of chromosomes and hence **aneuploidy** (unequal numbers of chromosomes). The reasons why aneuploidy results in cancer are discussed in Chapter 25.

FIGURE 18-36 Relation of centrosome duplication to the cell cycle. Centrosome duplication, which is initiated by the G_1/S phase CDKs and Plk4 (step **1**), results in the pair of centrioles (green) separating and a daughter centriole (blue) budding from each. By the G_2 phase, growth of the daughter centrioles is complete, but the two pairs of centrioles remain within a single centrosomal complex. Early in mitosis, driven by the activation of M phase CDKs (step **2**), the centrosome splits, each half nucleates assembly of microtubules, and the two centriole pairs are moved to opposite sides of the nucleus. The amount of pericentriolar material (green area around the centrioles) and the microtubule nucleation activity of the centrosomes increase greatly in mitosis. In mitosis, each MTOC is called a spindle pole.

There are a number of cases in which spindles form in the absence of centrosomes, including plant-cell mitosis and animal-cell meiosis in females. This observation implies that nucleation of microtubules from centrosomes is not the only way in which a spindle can form. Studies exploiting mitotic extracts from frog eggs — extracts that do not contain centrosomes — show that the addition of beads covered with DNA is sufficient to assemble a relatively normal mitotic spindle (Figure 18-37). In this system, the beads induce the assembly of microtubules, and factors in the extract cooperate to make a spindle. One of the factors necessary for this reaction is cytoplasmic dynein, which is proposed to bind to two microtubules and migrate to their (−) ends, thereby drawing them together.

Mitosis Can Be Divided into Five Stages

Mitosis is a carefully orchestrated process that proceeds through several stages, driven by the cell cycle circuitry, with each stage dependent on completion of the previous one (Figure 18-38). We first review events that occur in each of the stages, and then discuss some of the mechanisms that bring them about.

Torsten Wittmann, University of California, San Francisco.
Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 18-38 The stages of mitosis, followed by cytokinesis, in animal cells. Upper panels show stages in cultured cells stained blue for DNA and green for tubulin. Lower diagrams show the different stages and the events that occur in each.

Prophase is the first stage of mitosis. It is preceded by a number of coordinated and dramatic events that are necessary to assemble the spindle and prepare the cell for chromosome segregation and cell division. Some of these processes directly relate to chromosome segregation, while others facilitate mitosis or prepare the cell for the formation of two daughter cells. We discuss these two categories of processes in turn.

To prepare the microtubules for mitosis, the interphase array of microtubules is replaced as the duplicated centrosomes gain more pericentriolar material and become more active in microtubule nucleation. Because the assembly of microtubules radiating from these two MTOCs now resembles stars, they are often called mitotic **asters**. The dynamics of the growing microtubules increases due to changes in the activities of + TIPs at their (+) ends. Bipolar kinesin-5 (see Figure 18-20) walks toward the (+) ends of interdigitating microtubules, which slides them apart until the two asters come to lie on opposite sides of the nucleus (Figure 18-39a). The separated centrosomes will become the poles of the **mitotic spindle**, the microtubule-based structure that separates chromosomes. The cohesins holding together each pair of duplicated chromosomes, or **sister chromatids** as they are called at this stage, degrade except at the centromeric region, where the two sister chromatids remain linked by intact cohesins (Figure 18-39b). Also during prophase, specialized structures called **kinetochores**, which will become sites

of microtubule attachment, assemble at the centromeric region of each sister chromatid.

FIGURE 18-39 Separation of mitotic asters in prophase and parts of a condensed chromosome. (a) In prophase, the asters are separated by the bipolar kinesin-5 interacting with overlapping microtubules of opposite polarities. (b) Parts of a condensed chromosome in mitosis. The duplicated chromosome consists of two sister chromatids (each is a single DNA duplex), held together by cohesins at a constricted region called the *centromere*. The centromere is the site where the kinetochore, which will make attachments to the kinetochore microtubules, forms.

As noted, many cellular processes that are not directly related to chromosome segregation are dramatically altered in preparation for cell division. The internal membrane organization (which is normally dependent on the interphase array of microtubules) disassembles in preparation for the equal segregation of organelles into the two daughter cells. Endocytosis and exocytosis cease, and microfilaments rearrange to give rise to a rounded cell. In the

nucleus, the nucleolus breaks down and chromosomes begin to condense.

The next stage of mitosis, **prometaphase**, is signaled by disassembly of the nuclear pores and the nuclear lamina that underlies the nuclear envelope. This leads to breakdown of the nuclear envelope and its retraction into the endoplasmic reticulum. Loss of the nuclear envelope enables microtubules assembled from the spindle poles to search for and capture chromosome pairs by associating with their kinetochores. Each chromatid has a kinetochore, so a sister chromatid pair has two kinetochores (see Figure 18-39b). Microtubules from each spindle pole attach to one of the kinetochores. This attachment process is a critical step, which we discuss in detail shortly. The next stage, **metaphase**, is achieved when all the chromosome pairs align at a point equidistant between the two spindle poles.

When the cell detects that all chromosomes are attached to the spindle correctly, the next stage, **anaphase**, is induced by activation of the anaphase-promoting complex or cyclosome (APC/C) (discussed in Chapter 19). The activated APC/C ultimately leads to the destruction of the cohesins that were holding the sister chromatids together, so that each chromatid can be pulled to its respective pole by the microtubules attached to its kinetochore. This movement is known as *anaphase A*. A separate and distinct movement also occurs. The poles move farther apart, which

elongates the spindle in a process known as *anaphase B*. Now that the chromosomes have separated, the cell enters **telophase**, during which the nuclear envelope and nuclear lamina re-form, the chromosomes decondense, and the spindle disperses. Finally, the cell is pinched into two daughter cells by the contractile ring during **cytokinesis**.

The Mitotic Spindle Contains Three Classes of Microtubules

Before we discuss the mechanisms involved in the remarkable process of mitosis, it is important to examine the three classes of microtubules that emanate from the spindle poles. The *astral microtubules* extend from the spindle poles to the cell cortex (Figure 18-40). By interacting with the cortex, the astral microtubules perform the critical function of orienting the spindle to the axis of cell division. The *kinetochore microtubules* link the spindle poles to the kinetochores on sister chromatid pairs. During anaphase A, the kinetochore microtubules transport the newly separated chromosomes to their respective poles. The *polar microtubules* extend from each spindle pole toward the opposite pole and opposite-oriented polar microtubules interact in an antiparallel manner. As we mentioned, it is kinesin-5 walking along the polar microtubules that pushes the duplicated centrosomes apart during prophase.

FIGURE 18-40 Mitotic spindles have three distinct classes of microtubules. (a) In this high-voltage electron micrograph, a cell in metaphase was made permeable and microtubules were stained with biotin-tagged anti-tubulin antibodies to increase their visibility. The large cylindrical objects are

chromosomes. (b) Schematic diagram corresponding to the metaphase cell in (a). Three sets of microtubules (MTs) make up the mitotic apparatus. All the microtubules have their (−) ends at the poles. Astral microtubules project toward the cortex and are linked to it. Kinetochore microtubules are connected to chromosomes. Polar microtubules project toward the cell center with their distal (+) ends overlapping. The spindle pole with its associated microtubules is also known as a *mitotic aster*.

Microtubule Dynamics Increase Dramatically in Mitosis

Although we have drawn static images of the stages of mitosis, throughout mitosis microtubules are highly dynamic. As we have seen, as cells enter mitosis the ability of their centrosomes to nucleate the assembly of microtubules increases significantly (see Figure 18-36). In addition, microtubules become much more dynamic, allowing them to capture chromosomes and contribute to assembly of the spindle. How was this determined? In principle, one could label microtubules with a fluorescent tag and watch their individual behaviors, but practically speaking, there are too many microtubules in a mitotic spindle to follow individual ones. To get an average value for the dynamic instability of these microtubules, researchers introduced fluorescently labeled tubulin into cells undergoing mitosis, which became incorporated randomly into the cells' microtubules. They then bleached the fluorescent label in a small region of the mitotic spindle and measured the rate at which fluorescence came back using the technique known as *fluorescence*

recovery after photobleaching (FRAP) (see Figure 4-22). Since fluorescence recovery is due to the assembly of new microtubules from soluble fluorescent tubulin, the rate of recovery represents the average rate at which microtubules turn over. In a mitotic spindle, microtubule half-life is about 15 seconds, whereas in an interphase cell, it is about 5 minutes. It should be noted that these are bulk measurements and that individual microtubules can be more stable or dynamic, as we will see.

What makes microtubules more dynamic as the cell enters mitosis? As we discussed in Section 18.2, dynamic instability is a measure of the relative contributions of growth rates, shrinkage rates, catastrophes, and rescues (see Figure 18-9). Analysis of microtubule dynamics in vivo shows that the enhanced instability of individual microtubules in mitosis is generated mainly by an increase in catastrophes and a decrease in rescues, with little change in rates of growth (i.e., lengthening) or shrinkage (i.e., shortening). Studies with extracts from frog oocytes have suggested that the main factor enhancing catastrophes in both interphase and mitotic extracts is depolymerization by kinesin-13 proteins. This can be seen in an in vitro assay in which microtubule assembly from pure tubulin is nucleated from purified centrosomes (Figure 18-41a). If kinesin-13 is added to the assay, many fewer microtubules are formed. However, if the protein XMAP215, which enhances assembly at the (+) end, is added with the kinesin-13, many microtubules are formed due to a dramatic reduction in catastrophe frequency. It turns out that the

activity of kinesin-13 does not change significantly during the cell cycle, whereas the activity of XMAP215 is inhibited by phosphorylation during mitosis (Figure 18-41b). This results in much more unstable (more dynamic) microtubules as the cell enters mitosis (Figure 18-41c). This increase in dynamics is necessary to enhance the probability of chromosome capture by microtubules as described in the next section.

Chromosomes Are Captured and Oriented During Prometaphase

Kinetochores, the structures that mediate attachment between chromosomes and microtubules, assemble on each sister chromatid during prophase at a region called the centromere. The **centromere** is a constricted region of the condensed chromosome defined by a centromeric DNA sequence. Centromeric DNA can vary enormously in size; in budding yeast it is about 125 bp, whereas in humans it is on the order of 1 Mb (see Chapter 7). Kinetochores contain many protein complexes that facilitate the linkage between centromeric DNA and microtubules. In animal cells, the kinetochore consists of a centromeric DNA layer and inner and outer kinetochore layers, with the (+) ends of kinetochore microtubules terminating in the outer layer (Figure 18-42). Yeast kinetochores are attached by a single microtubule to their spindle pole, human kinetochores are attached by about 30 microtubules, and plant chromosomes are attached by hundreds.

FIGURE 18-42 The structure of a mammalian kinetochore. Diagram and electron micrograph of a mammalian kinetochore. The arrows indicate the ends of microtubules that insert into the kinetochore.

[Republished with permission from Springer, from B. F. McEwen et al., 1998, "A New Look at Kinetochore Structure in Vertebrate Somatic Cells Using High-Pressure Freezing and Freeze Substitution," *Chromosoma* **107**(6–7): 366–375; permission conveyed through Copyright Clearance Center, Inc.]

How does a kinetochore become attached to microtubules in prometaphase? Microtubules nucleated from the spindle poles are very dynamic, and when they contact a kinetochore, either laterally or at their ends, this contact can lead to chromosomal attachment (Figure 18-43a, steps **1a** and **1b**). Microtubules that capture kinetochores are selectively stabilized by a reduction in the rate of catastrophes, which increases the chance that the attachment will persist.

FIGURE 18-43 Chromosome capture and congression in prometaphase. (a) In the first stage of prometaphase, chromosomes become attached either to the end of a microtubule (**1a**) or to the side of a microtubule (**1b**). The chromosome is then drawn toward the spindle pole by dynein-dynactin that becomes associated with one of the kinetochores of the chromosome and moves toward the (–) end of the microtubule (**2**). Eventually, a microtubule from the opposite pole finds and becomes attached to the free kinetochore, and the chromosome is now said to be bi-oriented (**3**). The bi-oriented chromosomes then move to a central point between the spindle poles in a process known as *chromosome congression*. For ease of presentation, only single kinetochore microtubules are shown here. (b) Congression involves bidirectional oscillations of chromosomes, with one set of kinetochore microtubules shortening on one side of the chromosomes and the other set lengthening on the other. The kinetochore also contains many additional protein complexes not shown here.

Other studies have uncovered a mechanism involving Ran, a small GTPase, that enhances the chance that microtubules will encounter kinetochores. Recall that proteins destined for import into the nucleus associate with a nuclear import receptor, called an *importin* (see Figure 13-36). The complexes move from the cytosol through nuclear pores and into the nucleoplasm. The level of Ran·GTP is high in the nucleus, because its activator, the guanine nucleotide exchange factor for Ran (Ran-GEF), is localized there by binding to chromatin. In the nucleus, Ran·GTP binds to the importin, which changes the conformation of importin, causing it to release the transported protein. Then the importin-Ran·GTP complex leaves the nucleus through a nuclear pore to return to the cytosol.

In mitosis, Ran-GEF continues to associate with chromatin, so even after nuclear envelope breakdown there is a gradient of Ran·GTP around the chromosomes. This Ran·GTP releases a protein called *TPX* from importin. TPX binds the augmin complex and γ-TuRC and associates with the side of an existing microtubule to nucleate new microtubules at a shallow angle to the mother microtubule (see Figure 18-7c). This enhances the density of microtubules in the vicinity of chromosomes.

Once a kinetochore is attached laterally or terminally to a microtubule, dynein-dynactin associates with the kinetochore to move the duplicated chromosome down the microtubule toward the spindle pole. This movement eventually results in an end-on

attachment of the microtubule to one kinetochore (Figure 18-43a, step **2**). This movement helps orient the sister chromatid so that the unoccupied kinetochore on the opposite side is pointing toward the distal spindle pole. Eventually a microtubule from the distal pole will capture the free kinetochore; at this point the sister chromatid pair is said to be *bi-oriented* (Figure 18-43a, step **3**). With the two kinetochores attached to opposite poles, the duplicated chromosome is now under tension, being pulled in opposite directions by the two sets of kinetochore microtubules.

Duplicated Chromosomes Are Aligned by Motors and Microtubule Dynamics

During prometaphase, the chromosomes come to lie at the midpoint between the two spindle poles, called the *metaphase plate*, in a process known as chromosome *congression*. During this process, bi-oriented chromosome pairs often oscillate backward and forward before arriving at the metaphase plate. Chromosome congression involves the coordinated activity of several microtubule-based motors together with regulators of microtubule assembly and disassembly (Figure 18-43b). These regulators are localized at the kinetochores, but how they are maintained there is poorly understood — they are not part of the stable kinetochore complexes. The oscillating behavior of chromosomes involves lengthening of microtubules attached to one kinetochore and shortening of

microtubules attached to the other kinetochore, all without losing their attachments. In metazoans, several microtubule-based motors associated with the kinetochore contribute to this process. First, dynein-dynactin provides the strongest force, pulling the chromosome pair toward the more *distant* pole. This movement requires simultaneous shortening of the microtubule, which is enhanced by kinetochore-localized kinesin-13. The microtubules associated with the opposite kinetochore have to grow as the chromosome moves. Anchored at this kinetochore is the kinesin-related motor kinesin-7 (also known as *CENP-E*), which holds onto the growing (+) end of the lengthening microtubule. Also contributing to congression is another kinesin, chromokinesin/kinesin-4, which associates with the chromosome arms. Kinesin-4, a (+) end–directed motor, interacts with the polar and kinetochore microtubules to pull the chromosomes toward the center of the spindle and as a result, the chromosome arms point away from the closest spindle pole. When the chromosomes have congressed to the metaphase plate, dynein-dynactin is released from the kinetochores and streams down the kinetochore microtubules to the poles. These different activities and opposing forces work together to bring all the chromosomes to the metaphase plate, at which point the cell is ready for anaphase.

The Chromosomal Passenger Complex Regulates Microtubule Attachment at

Kinetochores

To have healthy daughter cells, the segregation of chromosomes at mitosis must be very accurate, so it is crucial that all chromosomes are bi-oriented before anaphase begins. During the random kinetochore-to-microtubule attachment process, it is possible for mistakes to be made. For example, both kinetochores of a sister chromatid pair might attach to microtubules from the same spindle pole. If such attachments persisted into anaphase, it would result in one cell missing a chromosome and the other having an extra one, which would either be lethal or very detrimental. Cells have two mechanisms to ensure that all chromosomes are correctly bi-oriented before anaphase begins. The first ensures that *each* individual chromosome is appropriately bi-oriented, and the second ensures that *all* of the chromosomes are properly bi-oriented.

The first mechanism works to ensure that the kinetochore-microtubule interactions are weak until bi-orientation occurs. When a chromosome is correctly bi-oriented, tension is produced across the chromosome, which leads to the kinetochore-microtubule attachments becoming stabilized. To understand how this works, we need to look a bit more closely at the molecular components that link a kinetochore to a microtubule. As we discussed in Chapter 7, kinetochores assemble on regions of chromosomal DNA marked by a centromere-specific H3 histone variant called *CENP-A*. This variant marks the site for kinetochore assembly. About half a dozen

distinct stable protein complexes, consisting of more than 40 different proteins, have been shown to associate with this centromeric region in yeast. Essentially all these protein complexes are conserved in humans, which is not surprising given the fundamental importance of kinetochores. One of these, the Ndc80 complex, is long and flexible, and many copies of it link the inner kinetochore with the (+) end of the microtubule in a sleevelike arrangement (Figure 18-44a). The function of Ndc80 and many of the associated factors at the kinetochore are regulated by the *chromosomal passenger complex (CPC)*. This complex associates with the inner kinetochore early in mitosis, and among its components is a protein kinase called *Aurora B*. Once the CPC associates with the kinetochore, Aurora B can phosphorylate several components in its vicinity, including the Ndc80 complex. This loosens the attachment of Ndc80 to the microtubule. The phosphorylation of these components is not stable, as the phosphatase PP1, which is associated with the outer kinetochore, can dephosphorylate them. Thus when the kinetochores on a pair of sister chromatids are not under tension, Ndc80 is continually phosphorylated by Aurora B and dephosphorylated by PP1. The result is a weakening of the interaction between the kinetochore and microtubule. However, when correct bi-orientation occurs, the microtubules pull in opposite directions on both kinetochores, creating tension across the chromosome. This extends the flexible Ndc80 complex, which increases the spacing between the inner and outer kinetochores (Figure 18-44b, c). As a result of these movements, Ndc80 cannot be

phosphorylated by Aurora B, and the dephosphorylated state of Ndc80 renders it more firmly attached to the microtubule. In this way, microtubule attachments to bi-oriented chromosomes are selectively stabilized.

FIGURE 18-44 CPC regulation of microtubule-kinetochore attachment. The Ndc80 complex forms a critical and regulated attachment between the kinetochore and microtubule (+) end. (a) Diagram showing the sleevelike arrangement of the Ndc80 complex linking the inner kinetochore to the (+) end of a microtubule embedded in the outer kinetochore. See S. Santaguida and A. Musacchio, 2009, *EMBO J.* **28**:2511–2531. (b) Diagram of the relationship between the chromosomal passenger complex (CPC), which is associated with the inner kinetochore and contains the kinase Aurora B, and the outer kinetochore, where the phosphatase PP1 binds. Notice that when both kinetochores are under tension, the outer kinetochores move away from the CPC; as a result, Aurora B cannot phosphorylate components in the outer kinetochore, which include the microtubule-binding site of the Ndc80 complex. (c) Cell in metaphase stained for tubulin (red), DNA (blue), Aurora B kinase (green), and the outer kinetochore (magenta). Notice how the outer kinetochore is pulled away from Aurora B (inset).
